Surgical Treatment of Ascites in Cirrhosis of the Liver.—Oresto Cignozzi gives the following conclusions from observations of the results of operative treatment of cirrhosis of the liver: (1) In affections of the trunk of the portal vein, with obliterating periendophlebitis from whatever cause, if ascites exists, surgical interference is justified, and good results can be expected. (2) In atrophic cirrhosis of alcoholic origin, except in the early stage, little belief is to be expected, and operation should be done in those cases only where life is threatened by hemorrhage into the stomach or bowels. (3) In alcoholic hypertrophic cirrhosis, the results are more encouraging. The ascites arises from a mechanical cause, and hence can be remedied. (4) In cirrhosis of cardiac origin the results are good. (5) In toxoinfective cirrhosis operation relieves ascites and stimulates the function of the liver. (6) In syphilitic, gummatous infiltration of the liver, good results are achieved, provided that the other organs are in good condition. (7) In malarial cirrhosis, of splenic origin, operation is useful.—*La Riforma Medica,* February 25, 1905.

Treatment of Puerperal Eclampsia by Parathyroidin.—G. Vassale has produced an extract of the thyroid body of special strength, which he calls parathyroidin or parathyreoantitoxin, and has used it in the treatment of eclampsia of pregnancy in three cases. The effect on the convulsions, he says, was surprising, such as to lead him to believe that it acts as an antitoxic toward the obscure cause of the eclampsia. He has also used it in a case of eclampsia in a child with good results, and in three cases of epilepsy, in two of which the convulsions were modified.—*Rivista Critica di Clinica Medica,* March 4, 1905.

Book Reviews.

THE CHANNELS OF INFECTION IN TUBERCULOSIS, together with the Conditions, Original or Acquired, which Render the Different Tissues Vulnerable. By HUGH WALSHAM, M.A., F.R.C.S., Physician to Out-Patients, City of London Hospital for Diseases of the Chest, etc. New York: William Wood & Co., 1905.

THIS monograph is the Weber-Parkes' Prize of the Royal College of Physicians of London for 1903. It consists of a discussion of various pertinent phases of the tuberculosis problem as based on the findings in some two hundred autopsies. It cannot be said that anything essentially new is brought out, but an accurate familiarity is displayed with the literature of the subject, and the matter is brought down to the basis of our present knowledge. For the author the scrofulous gland is the tuberculous gland, but the suppuration in the latter must not be ascribed to the bacillus; it is rather a mixed infection. From such foci, can the lung be infected by the gradual extension downward of the bacilli with the lymph stream? This the author regards as an open question. The general channels of infection are hereditary transmission, the lymphatic vessels, the blood vessels, epithelial channels, and inoculation. The second portion of the work considers the relations between tuberculosis and alcohol, diabetes, the various forms of cardiac disease, lymphadenoma, and cancer. A bibliography closes the book. The various principles the author considers as established are fortified by the histories of individual cases and illustrated by some unusually clear colored views of microscopical sections.

TEXT-BOOK OF INSANITY BASED ON CLINICAL OBSERVATIONS. By Dr. R. VON KRAFFT-EBING, late Professor of Psychiatry and Nervous Diseases in the University of Vienna. Authorized Translation from the Latest German Edition by CHARLES GILBERT CHADDOCK, M.D., Professor of Diseases of the Nervous System in the Marion-Sims-Beaumont College of Medicine, Medical Department of St. Louis University, St. Louis, Mo., etc. With an Introduction by FREDERICK PETERSON, M.D., President of the New York State Commission in Lunacy. Philadelphia: F. A. Davis Company, 1905.

KRAFFT-EBING'S well known text book of insanity has long deserved to be translated into English, and this want is supplied in the book before us. The author's clear exposition of psychology and psychopathology will make the English version especially useful to the student as well as to the practitioner. The present German edition follows the tradition of the preceding ones in the avoidance, as far as possible, of theories and hypotheses, in the emphasis of all that may be regarded as more or less certain in the science of psychiatry, and in the systematic arrangement of the scientific material. Owing to the peculiarity and the state of incompleteness of this science, psychiatric text-books usually present more or less prominently the standpoint of the author. The present work is the outcome of thirty-three years' observation and presents the disease-pictures in the light of the author's own experience. The book is well executed and well indexed.

THE MODERN MASTOID OPERATION. By FREDERICK WHITING, A.M., M.D., Professor of Otology, Cornell University Medical College; Aural Surgeon to the New York Eye and Ear Infirmary, etc., illustrated by twenty-five half-tone and twenty-three key plates, made from original drawings. Philadelphia: P. Blakiston's Son & Co., 1905.

THE appearance of an elaborate monograph on a single operation well illustrates the refinement to which modern surgery has been carried. The work of Dr. Whiting, however, fully justifies such a course, for we can speak of it only in the highest terms. It opens with a chapter on the historical development of mastoid surgery, particular attention being paid to the Wilde's incision. On the latter point, the general position taken is that lesions often occur in the osseous tissues before there are any changes evident in the periosteum, and the author affirms "wherever Wilde's incision is indicated a mastoid operation is imperative." He regards the services of Wilde as of moral value rather than clinical in that he roused otologists to the necessity and comparative safety of surgical intervention in ear diseases. The Schwartze operation is next discussed and is declared to be the foundation of modern mastoid surgery. This leads up to the definite views of the author, who styles his procedure the "complete" mastoid operation, a flap operation and 'complete' "in its intent to remove the entire cellular structure of the mastoid apophysis."

The remaining portion of the volume is devoted to directions for the proper technical performance of the complete operation. In successive chapters is discussed with the most minute details, every step from the initial incision to the post-operative care of the patient. Then follow chapters on indications for the operation and enumeration and description of the instruments required. Some pertinent conclusions suggested by the principles laid down form the concluding pages. A complete index is appended.

We have preferred to give an outline of the work, rather than to discuss individual matters suggested by its perusal. We have nothing but praise for it. The author has given particular attention to the needs of those who are called on to operate far from large institutions and medical centers and courteously calls attention to the error the beginner is apt to make as well as to the course he should follow. Special stress is laid upon the necessity of a thorough anatomical knowledge and a realization of the existence of anomalies in structure. This knowledge is presupposed on the part of the operator of the present day. He cannot evade responsibility in this direction and a patient must no longer be "condemned to convalescence because his sinus does not pursue in the temporal bone, the course prescribed for it by Gray's Anatomy."

A TEXTBOOK OF LEGAL MEDICINE. By EDWARD WIGGLESWORTH DRAPER, A.M., M.D. (Harv.). Professor of Legal Medicine in Harvard University; Medical Examiner for the County of Suffolk, Massachusetts; Medicolegal Pathologist at the Boston City Hospital, etc. Fully illustrated. Philadelphia, New York, London: W. B. Saunders & Company, 1905.

CONSIDERING the fact that every practitioner of medicine, no matter what his department of work may be, is likely at some time to have to appear in court as a medical witness, it is somewhat surprising that the number of books on forensic medicine is not larger. Of course, there are numerous good works on the subject available, but certainly no apologies need accompany the appearance of an addition to the number. The present volume is of a nature not to require excuses for its existence in any case, and, as its author was for twenty-eight years medical examiner for the city of Boston, it represents the fruits of unusual opportunities for observation. Both the legal and the medical aspects of forensic work are thoroughly discussed and the duties and rights of medical witnesses and experts clearly defined. The material is thoroughly modern in its treatment, as is shown by the discussion of the precipitin reaction in the section on the identification of blood stain and the author has not neglected the opportunities for good story telling afforded by the many illustrative cases cited.

THE TREATMENT OF NERVOUS DISEASE. By J. J. GRAHAM BROWN, M.D., F.R.C.P.E., F.R.S.E., Assistant Physician, Royal Infirmary of Edinburgh; Author of "Medical Diagnosis: A Manual of Clinical Methods." Fourth Edition. Edinburgh and London: William Green and Sons, 1905.

FOR those who desire to acquire practical information in an agreeable manner this book is to be warmly commended. The matter is presented in the form of lectures, though, as the author explains, these have been much added to since they were first delivered in the Royal Infirmary of Edinburgh. This is a literary form hard to carry through successfully, but in skilled hands it makes delightful reading, and the present author has made no mistake in adopting this semi-colloquial and unstilted style. Naturally the exhaustiveness of discussion to be expected in a formal treatise finds no place in the present volume, but much of interest and value is to be gleaned from its pages. The large print, wide margins, and excellent paper contribute much to the comfort of the reader.

UNTERSUCHUNGEN ÜBER KNOCHENARTERIEN, mittelst Röntgenaufnahmen injizierter Knochen und ihre Bedeutung für einzelne pathologische Vorgänge am Knochensystem. Von Dr. E. LEXER, a. o. Professor, Dr. KULIGA und Dr. WOLFG. TÜRK, früheren Volontäranistenten der königl. chirurg. Universitätsklinik Sr. Excellenz von Bergmann, Berlin. Mit 22 stereoskopischen Bildern und 3 Tafeln. Berlin: August Hirschwald, 1904.

THIS brochure contains a very interesting demonstration of the arteries in bone by means of Röntgen pictures of the injected vessels. A description of the technique of the injections precedes the presentation of the very beautiful plates. In addition to the plates, three in number, there are twenty-two stereoscopic pictures, by means of which the bones can be studied in their thickness, and the relative positions of the arterial twigs to each other become apparent. The value of such a demonstration to the surgeon and the pathologist is apparent.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held March 16, 1905.

THE PRESIDENT, DR. CHARLES L. DANA, IN THE CHAIR.

The evening was devoted to a discussion of the medical [illegible]

Prognosis of Gastric Ulcer Under Medical Treatment. — Dr. BEVERLEY ROBINSON said that his views and results of his experience had already been published in the MEDICAL RECORD and that he had little further to offer. His contribution to the discussion was based upon his personal experience in the treatment of ulcer of the stomach. Theoretically, the treatment of this condition belonged to the physician. There were few diseases to-day that had a more direct and positive interest to him than simple or round ulcer of the stomach, and he believed the condition could be cured by skillful intervention. If an ulcer should develop with pain and dyspeptic symptoms he believed a cure would follow from a purely medical course of treatment. But if the symptoms persisted then surgical aid should be invited which, in some instances, would save the patient's life. In cases of perforation of the stomach of any form of ulcer the indication was for operation, and the sooner the better. Instances of cure without surgical intervention, he said, were known but were very infrequent. Of 29 cases at St. Luke's Hospital, 24 occurred in females; of these 24, one patient died, 19 were cured, and the rest lost sight of. Only one of the 29 cases was treated surgically. Dr. Robinson said he had written to the representatives of many institutions to learn how many cases of ulcer of the stomach they had had, how many were operated upon, the nature of the operation, and the results obtained, as well as the results of stomach examinations before and after operation. The various reports received, he said, would take too long to present, and he did not believe were interesting enough to justify him in taking the time. In one institution there were 35 cases of gastric ulcer, 18 were operated upon, and 17 were under medical treatment. Ten deaths occurred among those operated upon, while none occurred among those treated medically. Most of the operations were emergency cases, and there were three gastroenterostomies. Dr. Erdmann had reported to him three cases; all recovered after operative interference. Dr. Adler had reported to him 43 cases occurring from 1900 to 1905, 39 medical and 4 surgical; 26 of the medical cases resulted in cure, practically without treatment; 10 were improved, and 10 unimproved. Some of the patients were victims of Bright's disease. One-third of them received nutritive enemata. In some of the operative cases the McGraw ligature was used with success. Dr. Lambert reported to him that from January, 1900, to January, 1905, there were 34 medical and 12 surgical cases. Dr. George P. Biggs reported a total of 78 cases, with 22 operated upon. Among the operative cases there were 10 deaths. At the New York Hospital during the past 10 years there were 52 cases of gastric ulcer, 35 being treated medically and 17 surgically. Of the 52 cases 11 died. Dr. Robinson said that statistics did not throw much light upon the subject of ulcer of the stomach except to point out the fact that surgical procedures offered, in some cases, the only road to recovery. He said that Dr. Blake reported 6 cases of perforation of the stomach in case of ulcer, with 3 recoveries and 3 deaths. Five cases were operated upon for gastric hemorrhage with 2 deaths and 3 recoveries. He believed the treatment of acute gastric ulcer was essentially medical, and hyperchlorhydria was the result and not the cause of ulcer. Robson, in 1901, had reported a 5 per cent. mortality in operations for gastric ulcer, and Moynihan had reported a mortality in gastroenterostomy as low as 2 per cent., and he thought these figures compared favorably with the mortality under medical treatment. The Johns Hopkins Hospital reports gave figures greatly in advance of those quoted. Mortality figures from different institutions varied greatly. The results obtained from treatment of hospital cases afforded no index of what would be expected in private practice, because these patients were badly cared for before entering the hospital, and operative interference was more often indicated. On the other hand, in private practice, the patients received the best advice from the onset of the trouble and were at once placed under proper diet and proper medication and, as a result, sooner or later they got well without the necessity for operation. In many cases in hospital work operative interference was delayed too long. The principles of medical treatment consisted chiefly in rest, bodily and mental, the use of rectal feeding with a gradual return to feeding by mouth. Special treatment for the accompanying anemia should not be ignored. Treatment of acute and chronic ulcer of the stomach differed; the acute cases could be cured by proper diet, rest in bed, with but few medicinal agents, but this treatment would not apply to the chronic cases. With regard to perforation and hemorrhage, he said the latter might be very profuse and alarming. He had but little if any faith in gelatin. Adrenalin, 10 to 20 drops of a 1 to 1,000 solution, was of value. If the hemorrhage was not readily controlled, operation should at once be resorted to. Examination of the gastric contents before and after operation was not made in this country except in a very few instances. Only two instances were on record at the Johns Hopkins Hospital. In both the total acidity was reduced. Dr. Robinson believed that if these patients received careful and judicious treatment they would rarely reach the stage where operation was indicated. Even in cases of profuse initial hemorrhage the hemorrhage might not occur again, and even if it did it would in all probability be less profuse. If two or more ulcers were found in the stomach it would be a dangerous procedure to excise them all. In some cases of sudden death from repeated hemorrhages he was of the opinion that some lives might be saved if artificial serum was injected either subcutaneously or intravenously prior to operation; this placed them in better shape to submit to operation with the hope of successful results. In conclusion Dr. Robinson presented certain facts: that probably there was no known treatment that would prevent the formation of fresh gastric ulcers; that uncertainty in diagnosis often led to clinical mistakes; that acute gastric ulcers must be recognized early clinically; that the treatment was purely medical; that in a certain proportion of cases this failed and chronic ulcers became established; that despite the brilliant results obtained from gastroenterostomies in gastric ulcer there were many objections to its performance; that in most cases he believed a conservative clinical diagnosis would enable us to form a judgment as to whether the treatment should be medical or surgical; that in emergency cases there frequently were no previous symptoms which permitted a probable diagnosis even; hence no rational preventive treatment in these cases could be carried out. Dr. Erdmann had reported 11 emergency cases in which there practically were no previous symptoms prior to perforation or severe hemorrhage for which he was called upon to operate.

The Late Results of Surgical Treatment of Gastric Ulcer. —Dr. JOHN C. MONRO of the Carney Hospital, Boston, read this paper. He believed the best results were obtained surgically and not medically, and that to-day a large part of the medical men in Boston were willing to admit this fact. The end results among 146 cases were known in 133 of them, but he regretted that he could not as yet give anything definite regarding the frequency of relapses, although he felt certain that risks of reformation of these ulcers were very small. Of these 146 cases there were about 50 of cancer; the remainder were benign lesions. In 14 cases of cancer and sarcoma the disease had advanced so far that a gastroenterostomy was not deemed advisable. Many of the cases had been under

medical treatment for a long time, and some were hopeless from the start. He said that he believed no one could tell with certainty the conditions of the viscera without opening the abdomen. In three of the cases a jejunostomy was performed to avert death from starvation. In 25 cases anastomosis was performed with the Murphy button. In five cases death was hastened by a few days, but the operation was done in each instance with the clear understanding that the outlook was desperate. With the less hopeless cases, he said, such signally good results had been obtained that he felt more and more encouraged. In 19 of these cases the final results were known; 2 patients lived over one year; 9 lived from one month to one year; the remainder died within one month after operation, but not directly as the result of the operation. The benefit of the operation appeared at once. When gastrectomy was done for cancer of the stomach he said he felt convinced that all of the growth could be removed. Two patients died as the result of imperfect technique, but since Mayo had improved the technique he expected better results. In four cases the results were very good, and it was interesting that but 4 cases out of the 50 came to them for operation in time for excision to be done. The patients did not seek surgical aid in time to get good results. Of the benign cases there were 90 operations and the end results were known in 78. In most of these cases medical treatment had been employed for periods extending over months or years. He said that Mayo had made the statement that he never operated upon a case of ulcer of the stomach unless it had been cured at least seven times. Primary cases were rarely operated upon. There were very few typical cases and he said that, as a result of his experience, he had grown quite accustomed to very startling revelations when opening the abdomen. Little help was to be had from either a bacteriological or a chemical examination of stomach contents. He said he had abandoned giving the test meal and preferred to give a good meal and note the results after a few hours. The general history of the condition, the bleeding, the distress, etc., made up the sum total in determining whether or not to interfere surgically. The diagnosis could not be made from visual and tactile examination alone, because the histology of the stomach was not known. Dr. Monro here described the operations performed. Finney's operation had not given good results and therefore had been abandoned. Moynihan's operation with the short loop gave the best results he had ever seen. In 11 cases in which the long loop was employed, 7 complete cures resulted. In all the anastomosis operations one should be very cautious regarding the dietary, and he said he had had cards printed for these patients' use informing them what they could eat, etc. In conclusion Dr. Monro said that the results of surgery in cases of ulcer of the stomach, as well as in malignant and benign growths, was certainly very encouraging. In both malignant and benign ulcers he believed that medicine must yield to surgery. One of the most important problems for solution to-day was the technique, and so soon as this was solved the results of operative work would be far better.

Dr. E. G. Janeway considered the question of lavage of the stomach in gastric ulcer and said that he had been called in consultation in two cases in which there were perforations as the result of lavage. Both patients were in a state of collapse and moribund and died. These two cases made a very strong impression upon him as to the advisability of washing out the stomach when one did not know the depth of the lesions. He referred to the statement made by a certain doctor that he had over 300 patients under treatment, and every day the stomachs of all were washed out until clean and then 100 to 200 grains of bismuth subnitrate were introduced and left; this man stated that he had not seen a single bad result from lavage. With regard to the employment of nitrate of silver, Dr. Janeway said he had seen one case in which argyria developed; this patient had cirrhosis of the liver and not ulcer of the stomach; he had a hemorrhage and the silver nitrate was given for the purpose of preventing another. Mistakes in diagnosis were often made and, sometimes, even when the abdomen was opened mistakes of diagnosis would be made. He referred to a case in which the diagnosis of malignant disease was made, the abdomen opened, the diagnosis confirmed by inspection, the abdomen closed and the patient made a recovery, the tumor entirely disappearing. He thought it might be interesting to note the number of cases of ulcer of the stomach in New York City which terminated fatally, and he gave the following statistics: In 1895, 71 cases, 43 males and 28 females; in 1896, 81 cases, 33 males and 48 females; in 1897, 65 cases, 32 males and 33 females; in 1898, 62 cases, 31 males and 31 females; in 1899, 71 cases, 34 males and 37 females; in 1900, 73 cases, 41 males and 32 females; in 1904, 93 cases, 51 males and 42 females. In all probability a large number of cases had not been recorded because not diagnosed.

Dr. George R. Lockwood said that of all diseases of the stomach ulcer was the most difficult to make any conclusions from in the way of statistics because there were so many cases that resembled ulcer which were not ulcers at all. There was nothing more difficult to diagnose at times than a neurosis and this was often mistaken for ulcer. Many cases of gastric ulcer were not treated at all until the terminal catastrophe occurred, such as rupture and hemorrhage; therefore the statistics given were very misleading, and one must rely almost entirely upon personal experience and the general impressions one got of the disease obtained in private and hospital practice, and not depend upon any statement of figures. The merits of any medical treatment could not be judged by hospital cases. He thought that all must agree that ulcer of the stomach at the pylorus should be treated not as an ulcer, but as a case of pyloric stenosis; that in cases of perforation the condition should be treated not as an ulcer, but as a case of perforative peritonitis. In those cases where there had been hemorrhages and pains, hypersecretion, etc., which complicated either an acute or chronic ulcer, he believed that much could be hoped for by rest in bed, hot applications (not cold) constantly applied, with absolute starvation so far as the stomach was concerned, for at least four days, with no nutritive enemata to stimulate peristalsis, and small doses of dessicated suprarenal, to be followed by Carlsbad treatment and enlargement of diet. He spoke of one case in which there was a relapse, but this was due to going out in the wet, catching cold, etc. In hospital cases one could not expect to get the same results as in private cases; often these cases before entering have repeated hemorrhages, or a continuance of the hypersecretion, giving rise to gastric distress, etc., so that when they did enter they were transferred to the surgical side.

Dr. C. E. Nammack said that Dr. Brooks had informed him that in 1,000 consecutive autopsies at Bellevue Hospital he had found 9 cases of gastric ulcer, and only two of these had been recognized during life. In cases of gastric ulcer he said hyperchlorhydria was present, and this condition tended to prevent the repair of these ulcers. The indications in treatment were to improve the nutrition, diminish the acidity of the gastric juice, and place the ulcer at rest, and success would attend our efforts in proportion as we were able to accomplish these measures. Treatment should not be addressed so much to the ulcer itself, but to its consequences. The acute form of ulcer was readily recognized and would yield to the medical treatment in the majority of the cases. Surgery had only to do with complications such as perforation and hemorrhage. Sixty cases were reported in which the nutritive enemata were entirely dispensed with and the patient got raw eggs and milk, and then after the sixth day scraped meat. He said that Dr. Lambert had advised enemata only for one week in acute cases, but longer in the chronic cases. He advised against mistaking acute exacerbations occurring in chronic ulcer for acute ulcer. In 87 per cent. of the cases in which chronic ulcer occurred it

was solitary and, therefore, more amenable to surgical intervention.

Dr. Max Einhorn said that after gastroenterostomies for gastric ulcer the patients ultimately would return complaining of an intense hyperchlorhydria, and it should not be believed that this operation was a cure-all; even in cases of pyloric obstruction surgical operation should not be resorted to always. The mortality rate to-day was too high in these operations; if it could be kept as low as 1 per cent. he then thought surgery would more often be resorted to. Because of the high mortality rate, *i. e.* comparatively speaking about 10 per cent., he did not think patients with gastric ulcer should be urged to undergo surgical treatment when it was possible to let them live for months or even years in comparative comfort under medical treatment. He spoke of the difficulty encountered in making a positive diagnosis of ulcer of the stomach; even when hemorrhage was present it might be a parenchymatous hemorrhage or a leakage. Cases had been reported in which operations had been done for gastric ulcer and yet none was found. The mortality in surgical intervention was great as a rule, because of the lowered vitality of the patient. Operation was usually advised when the hemorrhage was not very great; we should not wait until it was so profuse as to make any operative work too risky. Dr. Einhorn believed that even in those cases where the hemorrhage was very profuse and where the patients appeared to be absolutely lost, they would in a great many instances get well without operation. He believed that it was a risky thing to wash the stomach out in cases of ulcer. The washing out or emptying of the stomach was not necessary, because this viscus, in cases of ulcer, was empty anyway. The treatment should consist in rest in bed with some of the milder forms of liquid diet, or else nothing by mouth and rectal alimentation, especially in the chronic types. Large doses of bismuth he believed to be of benefit. It should be given in one-half drachm doses three times a day and in a little water.

Dr. George E. Brewer said that it was quite significant that no New York surgeon had as yet reported any large series of operations upon the stomach; Mikulicz, Mayo Robson, Moynihan, Mayo, and surgeons in Philadelphia, Boston, and other places, had furnished reports of operations for gastric ulcer, but no one had as yet from New York. The same questions had arisen with regard to operative procedures in gastric ulcer that arose twenty years ago in appendicitis when the idea of operating upon any but moribund cases was scouted until it was shown in a large series of cases that the mortality was greater with medical treatment. Dr. Brewer believed that within ten years general practitioners would be as eager to have the majority of gastric ulcers treated surgically as they were eager to have operation upon the appendix in the early stages. Many cases to-day were treated as cases of dyspepsia, or gastric neuroses, and these patients went from doctor to doctor without the true nature of the condition being known until the case developed into one of chronic gastric ulcer. All admitted that cases of perforation should be treated surgically from the start; these patients almost invariably died if treated by other than surgical means. Again all admitted that cases of grave and repeated hemorrhages from the stomach should be treated surgically. Gastric ulcer with pyloric stenosis should be treated surgically. Surgical treatment should be employed in cases of mechanical obstruction, which caused gastric dilatation and fermentation, vomiting and emaciation. It was not a question of chemical, but one of physical indications. Another form of gastric ulcer which he thought should be turned over to the surgeon, was the intractable ulcer of the stomach, the one that would not yield to medical treatment. In these cases the dyspectic and other symptoms disappeared like magic when a gastroenterostomy was performed. The great difficulty in diagnosis was admitted by all, and no one was better able to know this fact than the surgeon who so often opened the abdomen. With regard to statistics, one must rely upon them when they came from reliable men. In a paper read before the American Medical Association, Dr. Howard of Baltimore said that accurate records were kept at the Johns Hopkins Hospital, and he was able to state that at the time of discharge, 14 per cent. were apparently cured. A large number were improved, and a large number subsequently developed symptoms of a recurrence. The mortality was something like 29 per cent. for all cases. Dr. Brewer thought that we now were in the transition stage regarding ulcer of the stomach, the same as surgeons once were in the treatment of appendicitis and intestinal obstruction.

Dr. Jos. A. Blake emphasized the importance of early operation in cases of perforation from gastric ulcer, and said that one should not think of waiting until shock disappeared; shock would disappear with the administration of the anesthetic. Many cases of perforation did not give antecedent symptoms, because the ulcers were not situated in the motor area of the stomach. The symptom-bearing ulcers were situated near the pylorus, and, consequently, were more amenable to surgical treatment. The treatment that cured was *rest*, and, therefore, cure would not follow when the patients were fed, the food passing over the ulcer. The best means of gaining this complete rest was by doing a gastroenterostomy. He spoke of the cases that had been reported in which Nature had attempted a cure; for instance, a loop of the ileum had become adherent to the wall of the stomach at the site of the ulcer, and the ulcer had opened through it; in such cases Nature performed a gastroenterostomy. Early diagnosis and operation would often save cases that seemed to be hopeless. A single large gastric hemorrhage in a young woman, he said, was likely to be from an acute ulcer of the stomach.

Dr. Harlow Brooks gave a demonstration of pathological specimens illustrating gastric ulcer.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, February 7, 1905.

The President, Dr. Joseph Fraenkel, in the Chair.

Two Cases of Dysbasia Angiosclerotica (Intermittent Claudication), with Demonstration of Calcareous Deposits in the Pedal Arteries.—Dr. J. Ramsay Hunt presented three patients and illustrated the report by radiographs taken by Dr. Arthur Holding. The first patient was a man, 49 years old. His occupation for the past thirty-two years had been that of an iceman, which necessitated long and frequent exposure of the feet to cold and wet. The patient had used alcohol and tobacco to excess for many years. He acquired syphilis in 1879. The following year he had some ulcerations on the right leg, and five years later suffered from ulceration of the palate, with perforation. In September, 1903, he had an attack of delirium tremens, for which he was treated in the alcoholic pavilion of Bellevue Hospital. Restraint was necessary, and he was bound in the usual manner by sheets attached to the wrists and ankles. The first symptoms of the present affection appeared immediately after his discharge from the hospital, and was attributed by the patient to the restraint used. He complained of stiffness in the toes, the left leg, and the ankle, and paresthesia of the toes and edges of the feet. After walking a quarter of a mile, the prickling pain and stiffness became so distressing that he had to sit down until it wore off, which was the case after a few minutes' rest. His symptoms were much worse in winter than in summer, and were especially severe on a cold day. On rising in the morning, the feet and legs felt perfectly well and natural. Toward the end of the day the feet became puffed up and swollen, and presented a mottled and cyanotic hue. He complained that they felt cold most of the time. The posterior tibial artery was not palpable on either side. The dorsalis pedis was full, and larger than normal. The

femorals and popliteals pulsated normally on the two sides. The feet were cold, and on standing became red and swollen, with a distinct purplish tinge. Numerous venules and minute venous varicosities were present about both ankles, and along the anterior tibial region. The toe-nails on the left foot presented transverse ridges. The reflexes and sensation of the lower extremities were normal. Signs of a general arteriosclerosis were present, and the urine contained a faint trace of albumin, but no casts nor sugar. Its specific gravity was 1017. Subsequent examination revealed an occasional faint pulsation in both posterior tibials, weaker on the left side.

The second patient was a man 60 years old, who for fifteen years had been a longshoreman. For the past ten years he had worked in bar-rooms, where his feet had been exposed a good deal to the cold and wet. He denied lues. For the past fifteen years, he had smoked from ten to fifteen cigars daily, and had used alcohol to excess. About five years ago he began to suffer from numbness, stiffness, and a cold sensation in the toes of the right foot, coming on about two hours after beginning work in the morning. At the end of the first year he was compelled to rest after about three hours. At the end of two years his condition had grown worse; the paresthesia and stiffness had extended as high as the ankle, and rest was necessary after two hours' work. After resting, and in the morning on arising, all his symptoms had disappeared. The symptoms in the left foot gradually grew worse, and six months ago similar symptoms appeared in the right foot, beginning in the toes. Both feet assumed a mottled appearance on standing, but did not swell. A pulsation of the femorals, popliteals, and posterior tibials could be felt on both sides, while the pulsation of the dorsalis pedis was entirely absent on both sides, although the artery could be felt as a fine rounded cord. The reflexes and sensations of the lower extremities were normal. There were well-marked signs of a generalized arteriosclerosis. The urine had a specific gravity of 1023: it contained a trace of albumin; to sugar. The symptoms presented in the cases shown were to be ascribed to an arteriosclerosis of the vessels of the leg and foot—the so-called dysbasia angiosclerotica (intermittent claudication of Charcot). The *x*-ray photographs demonstrated by Dr. Holding showed very exquisitely deposits of lime in the posterior and anterior tibial arteries and the dorsalis pedis, marking out very definitely the course of the vessels. As might be inferred from the general evidences of arteriosclerosis in both cases, the pathological process in the pedal arteries was the usual arteriosclerosis of Gull and Sutton, with deposits of lime in the media. These cases are supposed to be less amenable to treatment than the endarteritis forms; hence this method of demonstration might have a certain prognostic value. Both cases had shown a very moderate response to treatment.

Dr. S. Sachs called attention to the similarity of the lesions met with in this condition to those of erythromelalgia.

A Case of Probable Infectious Myelitis of the Cervical Region, Following a Compound Fracture of the Jaw.—Dr. J. Ramsay Hunt, presented this patient, a man 36 years old, a painter by occupation, who, until the onset of the present trouble, had enjoyed excellent health. He had never shown any symptoms of lead poisoning. On December 7, 1904, he fell on the street and fractured [illegible] jaw in two places. The fracture was a compound one, and the wound, which was on the inside of the mouth, bled for several hours. Three weeks later he had rigors at night, on one occasion followed by profuse perspiration. On January 5, 1905, after a heavy slumber, he awoke with severe pain in both arms, which were also very weak, so that he could hardly lift them. The weakness was chiefly in the muscles of the shoulder, especially on the left side. The pains continued all day with great severity, sharp and lancinating in character, and shooting through the whole length of the arms, although more severe in the shoulders. The next morning the pains had ceased entirely in the right arm, and the power in the extremity had returned. He was unable, however, to elevate his left arm, and the severe pains still continued, especially in the region of the left shoulder. There were no vesical symptoms. For several nights following the onset of the paralysis he had chills of moderate severity. The patient was first seen by Dr. Hunt on January 20, 1905, two weeks after the onset of the symptoms. He still complained of sharp, shooting pains in the region of the left shoulder, and the deltoid muscle was somewhat tender to deep pressure. It might be added, however, that on compressing the muscle bundles of the deltoid between the fingers, the same pain and tenderness were elicited as on deep pressure. The nerve plexus above the clavicle and the axilla and along the inner side of the arm was absolutely free from any tenderness. The left arm was the seat of a slight general atrophy which was very marked in the deltoid muscle. All movements of the left arm and shoulder could be carried out with practically normal power, excepting adduction of the arm. On attempting adduction, some of the posterior bundles of the deltoid were felt to contract, but little or no movement of the extremity was produced. All the arm jerks were present, and were equal on the two sides. On testing the sensibility it was found that the tactile, pain, and temperature senses were retained over both upper extremities, and that the deep sensibility was also normal. A more careful sensory test, however, showed that the sensation was relatively diminished for pain, temperature, and touch along the outer side of the arm from the shoulder to the wrist, corresponding very closely to the recognized sensory distribution of the fifth cervical segment of the cord. In the right arm, a similar relative obtunding of sensation was also present, but less marked and not so extensive, being practically limited to the region of the deltoid. The gross motor power and tendon reflexes of the lower extremities were normal. The Babinsky phenomenon was absent. The deltoid muscle failed to respond at Erb's point to the galvanic or faradic current, although good contractions were produced in the biceps and the supinator longus. The direct faradic current produced a sluggish response in the posterior portion of the deltoid; no response in the anterior half. By the direct galvanic current a slow, vermicular response was elicited, with reversal of the poles. The urine contained some albumin and hyaline casts. A blood-count showed 4,112,000 red blood corpuscles; 10,000 white cells, and 75 per cent. of hemaglobin. The erythrocytes were normal; no granular basophilia. The differential count was as follows: polymorphonuclears, 70.6 per cent.; lymphocytes, 10.2 per cent.; large mononuclears, 18.8 per cent.; eosinophiles, 0; mast cells, 0.4 per cent. On February 1, 1905, the patient still complained of a dull aching, with occasional sharp, shooting pains in the left shoulder. The moderate tenderness in this region still persisted. The gross motor power of the deltoid had greatly improved, so that the arm might now be elevated above the head. This occurred chiefly through the medium of the posterior half of the deltoid muscle, the anterior portion remaining entirely relaxed and flaccid. The slight sensory changes still persisted. There was no Babinsky reflex. A piece of dead bone had been removed from the inside of the mouth, and the breath and secretions of the mouth were very fetid. The interesting features of this case, Dr. Hunt said, were those of localization and etiology. Considering the patient's previous good health and the absence of any other demonstrable cause, it was natural to refer the symptoms to the suppuration and the carious process in the lower jaw, more especially as mild symptoms of sepsis directly preceded and followed the onset. While the persistent pains and apparent tenderness over the left deltoid might suggest a neuritis of the circumflex nerve, it might be emphasized that the paralysis of the deltoid was incomplete, and evidences of objective sensory changes limited to the circumflex were absent. The speaker also emphasized the absence of tenderness or other evidences of inflammation in the plexuses and cellu-

lar structures of the neck. On the other hand, the initial paralysis and severe pains, symmetrical and bilateral in distribution, the rather sudden recovery of the right arm and the more gradual recovery in the left; the unequal distribution of the paralysis in the left deltoid, and the gradual improvement which this paralysis had undergone; the relative diminution of sensation on both sides in an area corresponding very closely to that of the fifth cervical segment, all pointed strongly to a central cord lesion. The nature of this case could only be inferred. A poliomyelitis or a myelitis of infectious organ naturally suggested itself.

Dr. Charles L. Dana said he had seen Dr. Hunt's patient some days ago, when there was still some paralysis of the left arm. The condition could best be explained on the theory of a thrombosis plugging one of the central arteries and affecting the left anterior horn, about the region of the fifth cervical segment.

Dr. Fraenkel said there were a number of cases reported in literature where septic conditions, particularly that known as angina Ludovici—an acute suppurative condition of the connective tissues of the neck—had given rise to a septic neuritis. The speaker said he saw such a case in consultation about three years ago. The case was one of a septic throat condition, and eight or ten days later, after the acute symptoms had subsided, there were evidences of a bilateral brachial neuritis. It began with severe pain, in that way differing from the case shown by Dr. Hunt.

Address of the Retiring President.—Dr. Pearce Bailey stated in his address that while the membership of the society had been materially enlarged during the past year, notably by younger men, the new members had not shown the active participation in the proceedings which was absolutely essential for the society's continued prosperity. Many interesting cases had been shown during the year, and the [illegible] had brought out large audiences and had been fruitful in valuable information. While individual clinical cases and general discussions perfected the art of the clinician, they did not give neurology all that neurology had a right to expect from as representative a body as the New York Neurological Society. For the science to be advanced, more fundamental contributions were essential. It was commonly said, and with much truth, that neurology was living to-day on its past achievements. So much the more necessary was it to try to give it new life, to start it again on that progress which, only a few years ago, made it the most brilliant branch of medicine.

Address of the President-Elect.—Dr. Joseph Fraenkel delivered this address. (See page 481.)

Philadelphia Neurological Society.

At a stated meeting held February 28, Dr. D. J. McCarthy exhibited "A Case of Tuberculosis with Graves' Syndrome." The patient was a woman of perhaps 40 years, who had for two years presented symptoms of pulmonary tuberculosis and within a few months had developed transitory and recurring enlargement of the thyroid gland, with tachycardia, tremor, retraction of the upper eyelids and imperfect descent of the upper lid with the eyeball, but without exophthalmos. Dr. McCarthy further stated that a considerable number of cases of similar character had come under observation at the Phipps Institute for Tuberculosis, and it was a question whether they were true examples of Graves' disease or a symptom-complex, perhaps of toxic origin, simulating that disorder. Dr. Ralph Pemberton exhibited for Dr. W. G. Spiller "A Case of Lumbothoracic Syringomyelia." The patient was an Italian woman some 35 years of age who presented spasticity in the left lower extremity, with exaggeration of the reflexes, and weakness, with abolition of the reflexes and sensory dissociation in the right lower extremity. The upper extremities and the trunk were unaffected. Dr. W. G. Spiller exhibited "A Case of Progressive Muscular Dystrophy with Atrophy of Bone." The patient was a man about 25 years old in whom weakness and muscular deficiency had been observed from the age of 2 years following an injury to the back by falling lumber. The symptoms became much exaggerated at the age of 16 years, and at the present time the muscular tissue was deficient in extreme degree in some situations, including the face, and the bones themselves were attenuated, as could be seen also in skiagrams. The disturbance was entirely asymmetrical, with respect both to musculature and to bone. Dr. Spiller exhibited also "A Case of Chronic Mercurial Intoxication." The patient was a hatter employed in a room where felt impregnated with mercury was being constantly cut, and who in addition to inflammatory changes in the gums presented also marked tremor increased with repeated voluntary muscular action and exaggerated knee-jerks. Dr. Spiller exhibited further "A Case of Tabetic Facial Palsy." The patient was a man about 45 years of age, with a syphilitic history, who presented characteristic symptoms of tabes and in addition paresis of the left side of the face, of which he had himself been unaware. There was no history of acute invasion or of exposure to cold as a causative factor, and it was believed that the state of the facial muscles represented a complication of the spinal disorder and not merely an intercurrent affection. Dr. T. H. Weisenburg exhibited "A Case of Hemorrhage into the Pons," occurring in a man 35 years old who had struck his head in falling from a trolley-car. He was unconscious for a few days and on returning to consciousness it was found that there was double vision. Examination at a later date disclosed the existence of paralysis of the external rectus muscle of the right eye, with wasting and fibrillary twitching of the right half of the tongue and of the muscles of the right side of the face, and impairment of sensibility in the distribution of the right fifth nerve. Dr. Weisenburg exhibited also "A Case of Hemorrhage into the Floor of the Aqueduct of Sylvius." The patient was a farmer 55 years old who had suddenly observed drooping of the upper lid of each eye with loss of the power of elevation, and who on examination was found to present paralysis of the muscles supplied by the third and fourth cranial nerves. Dr. Ralph Pemberton reported a case of strychnine poisoning with convulsions, in which 1½ or 2 grains of the drug had been taken, and also a case of lead poisoning with wrist drop and intestinal colic in both of which the Babinski reflex was present. Dr. George E. Price read a communication entitled "A Case of Malarial Infection Presenting Symptoms of Multiple Neuritis." The patient was a girl 8 years old who had had symptoms of malarial fever for 18 months and presented tremor, muscular weakness, and diminished reflexes. Malarial plasmodia of the estivoautumnal type were found in the blood, and all of the symptoms disappeared under the administration of quinine. Dr. Alfred Gordon read a paper entitled "Clinical and Pathological Report of a Case of Lead-poisoning with Remarks on the Pathogenesis of the Disease." He reported the case of a man suffering from wrist drop and intestinal colic and with a history of a previous attack of similar character. Death took place suddenly, and while post-mortem examination failed to disclose any macroscopical alteration in the nervous system, histological study revealed the presence of degenerative changes in the peripheral nerves, the spinal nerve-roots, the cells of the anterior horns and in the posterior columns, together with sclerotic alterations in the blood-vessel of the cord. The opinion accordingly was expressed that the deleterious effects of lead are not confined to any one portion of the nervous system, but are expended on all.

Influenza.—Wolfe recommends for the muscular and joint pains of this condition the following lotion:

℞	Pot. Carb	℥ss
	Tr. Bellad	℥ss
	Aq. Camph. q. s. ad	℥iv

Sig. Apply every hour. —*Penn. Medical Journal.*

Joint Meeting of the Chicago Urological and Chicago Medical Societies.

At a meeting held March 1, 1905, Dr. William T. Belfield read a paper on "Pus Infections of the Genital Tract in the Male," and said they are induced by the gonococcus and by the common pyogenic bacteria. To the latter the healthy urethra was immune, since they were found as constantly in the average urethra as in the average mouth. They invaded the urethral tissues when the vitality of the latter was reduced by stricture formation or by senility. The genital duct proper—seminal vesicle, vas deferens, and epididymis—reacted to the pyogenic bacteria just as did the urethra, that is, by suppuration. This fact had been hitherto overlooked, and gonorrheal epididymitis was to-day treated as a medical rather than as a surgical disease, probably because fluctuation in the epididymis was so seldom recognized. The author's investigations had shown that the pus infections of the male genital duct were quite analogous to those of the Fallopian tubes; that pus tubes were quite as common in the male as they were known to be in the female; and that acute epididymitis, gonorrheal or otherwise, should be treated as a suppurative process, by incision and drainage. While this might be omitted in the mild cases, it should be practised in the severe grades, especially when acute hydrocele and scrotal edema appeared, for these were infallible signs of suppuration. In chronic epididymitis, especially when a painful and tender swelling persisted in the epididymis, incision or excision of the pus focus might be required. The author had practised a therapeutic measure which seemed to be novel, namely, injection into the entire vas deferens and seminal vesicle through a needle introduced into the vas, just above the epididymis. The therapeutic value of this measure was yet to be determined. At present it was merely asserted that the mucous lining of the vas and seminal vesicle could be medicated in this way.

Dr. Arthur Dean Bevan discussed "X-rays as a Means of Diagnosis in Kidney Surgery." He thought the best exposition of this work was to be found in a comparatively recent number of the *Beiträge für Chirurgie,* from the pens of Kümmel and Rumpell. These gentlemen took the position of Leonard and the speaker that the *x*-ray, properly used, would detect a stone in any individual, no matter how thick, and a stone of any chemical composition; that the detection of the stone did not depend so much upon its chemical composition or the thickness of the individual as it did upon the proper use of the *x*-ray. The speaker reported 27 cases last year which he had treated, and the results up to that time were the following: In 13 cases positive findings, and stone was found at operation; in about the same number of cases, negative findings, and at the operation other pathological conditions than stone were found.

Dr. M. L. Harris spoke on the diagnosis of ureteral stones, and called attention to the possibility of error in interpreting shadows which apparently lay in the course of the ureter, and particularly that portion of the ureter which was contained within the pelvis. He had had two interesting cases recently in which an error of interpretation of the significance of distinct shadows in this portion of the pelvis was made. These two cases were cited in detail, and showed how easy it was to make an error in diagnosis by depending on the *x*-ray alone in supposed ureteral stones. What the cause of these shadows was still remained a mystery. Whether they were due to phleboliths or to small sesamoids or spots of calcification in some of the muscles of the pelvis, he was unable to say, but that they were not due to ureteral stones was certain, and that such shadows could not by their appearance alone be distinguished from ureteral stones was equally true. When such shadows were found in this portion of the pelvis, with symptoms pointing to ureteral stone, the ureters should be catheterized to determine whether the shadow actually lay in the course of the ureter, and whether the catheter met an obstruction at the point indicated. The tip of the bougie might be waxed, so that contact with a foreign body, such as stone, might be recognized by the indentations made in the wax. It was not his intention to deprecate the value of the *x*-ray in this work, but to call attention to the fact that there might be other bodies in the pelvis capable of casting shadows which, from appearance alone, could not be distinguished from shadows cast by ureteral stones, and that in some of these cases a correct diagnosis could be made only by the use of the ureteral bougie.

Drs. Gustav Kolischer and Louis E. Schmidt read a joint paper on "An Attempt to Use the Electric Conductivity of Urine for Clinical Purposes." The authors tried to make every kidney a standard unto itself, and started from the idea that the vitality and normal and abnormal status of any tissue could best be tested by observing its reactions to certain interferences brought to bear upon it. Beginning from the experience that certain stains brought into the circulation, would appear at different times and with different intensity in the urine, they investigated whether or not the secreting efficiency of normal and abnormal kidneys might be influenced in a way peculiar and characteristic of normal and abnormal conditions of the secreting tissue. If that were the case, the osmotic concentration of the urine voided before and after staining certainly ought to show marked differences. The results of their investigations so far would seem to bear out these theoretical speculations. As the most sensitive test, they resorted to the test of electric conductivity, and as a method of staining they selected hypodermic injections of indigo carmine. After the stain was brought into the circulation, and after the urine became colored, the urine of normal kidneys always showed a slight decrease of electric conductivity which depression, however, would never exceed nine international ohms. In case the urines simultaneously drawn from both normal kidneys showed different electric conductivity before staining, the decrease of conductivity appearing after staining was exactly the same in either specimen. So far, the authors believed they were justified in saying that any increase after staining of electric conductivity beyond ten international ohms was characteristic of impaired health of the kidneys. If this increase remained inside the limits of twenty ohms, the kidney might be considered safe in a surgical sense, that is, it could reasonably be expected to be of sufficient functional capacity to attend to the eliminating process after its mate had been removed. Any kidney whose urine after staining showed an increase of electric conductivity beyond twenty ohms, had to be considered as absolutely unsafe in a surgical sense. If this method should prove to be reliable, the authors said, they would have succeeded in determining the fact that there are cases of one-sided nephritis. They hoped they would be able to determine by this method in advance whether a given individual would react as to his kidneys favorably or unfavorably to the administration of a general anesthetic. Dr. B. C. Corbus demonstrated an apparatus for testing the electric conductivity of urine.

Dr. R. R. Campbell spoke on the "Diagnosis of Syphiloma of the Kidneys." He pointed out the possibility of gumma of the kidneys, especially when dealing with surgical kidney, and whether the amount of blood and débris was large or small, it should cause one to consider surgical interference. In establishing the diagnosis of syphiloma of the kidney, if the gumma or gummata were of large size, the kidney with these irregularities might be palpated. There might be cachexia present; the patient might naturally have lost in weight. With all these signs and symptoms, it became necessary to differentiate from a malignant growth. The indolent character and the benign course of such a tumor always spoke for a luetic cause. Wherever these findings were present, a nephrectomy should not be done until the possibility of syphilis was excluded.

Chicago Medical Examiners' Association

At a meeting held February 27, 1905, Dr. James Nevins Hyde read a paper entitled "Syphilis as Related to the Problems of Longevity." He drew the following conclusions: (1) Syphilis, like unmodified variola and tuberculosis,

may destroy life. In its gravest expression, when not destructive of life, it may disfigure and mutilate the human body to a formidable extent. The disease should be counted among the dangerous scourges of the human family. Once in the presence of infection, neither physician nor patient can afford to neglect skillful, energetic, and prolonged treatment, with a view to setting aside the possibilities of future danger. (2) In the case of inherited syphilis, the fatality, working destruction alike of ovum, fetus, and infant, varies between eighty and ninety per cent. of the infected. The mortality, exceeding that resulting from any of the great plagues of the human race, is due to the unprotected condition of the embryo. (3) By reason of the absence of trustworthy statistics, the percentage of fatality in acquired syphilis, where the germ of the disease is implanted upon a previously sound organism, cannot be accurately determined Estimates based upon clinical records furnished in the larger cities of the United States, coupled with the facts detailed in the volumes of vital statistics published by the United States Census Bureau, make it appear probable that the fatality in such acquired disease is represented by a percentage of less than two per cent. (4) The fatality in acquired syphilis results less often from the active invasion of the disease than from an entailed loss of resistance, by reason of which common agencies of disease produce serious effects, especially in the nervous system. (5) The efficient factors in the production of these effects are fairly well understood. They include chronic alcoholism, long-continued tobacco-narcosis, extreme fatigue, severe affliction, the malnutrition that may result from poverty, the stress and strain endured by the nervous centers in the anxieties of business. (6) In the absence of these efficient factors in the production of the grave conditions which may follow syphilis, the skillful management of that disease may terminate with brilliant results in from seventy-five to eighty per cent. of acquired cases. (7) The damage wrought by syphilis is not to be measured solely by its lethal issues, though these are of chief concern to the life insurance actuary. The lowering of the standard of average health wrought by the inroads of the malady, often appreciable in the skin, bones, testes, liver, and other organs, and the moral results of the acquisition of a disease popularly described as "loathsome," may jeopard the best play of the body functions, pave the way for the inroads of other toxins, and possibly lay the foundation for mental degeneration, alienation, and even suicide. (8) The expectation of life, after acquisition of syphilis, is based in part only upon the tendencies of the morbid process. Such expectation is in large measure affected by the inherited tendencies, the habits of life, and the environment of the individual. The longevity prospects are unquestionably better for women than men, by reason of the relative placidity of existence of the former. Briefly, the medical examiner confronted with a history of syphilis in an applicant for life insurance, should be influenced in acceptance or rejection of the risk not merely by the historical facts of the case, including the character of the symptoms exhibited, and the duration of time since the last objective manifestations of the disorder were recorded, but especially by the reasons which would lead to his acceptance or rejection of applicants giving a history of other enfeebling maladies. The ideal applicant for life insurance who has suffered from syphilis should have had active and unmistakable symptoms of that disease early in life; should have had, after efficient treatment, several years of exemption from all evidences of infection; should have an excellent family history, free in particular from instances of nervous diseases affecting immediate relatives; and should be leading, and have led, a life relatively free from strain, stress, and excess of all kinds, including indulgence in alcohol, tobacco, or other of the narcotic stimulants.

Culinary Typhoid Fever.—After a club dinner at a hotel in Stockholm, recently, several score of persons were taken ill with typhoid fever, due to unfiltered river water that had been used for the washing of the salad.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE MEDICAL EPITOME SERIES. MEDICAL DIAGNOSIS. By AUSTIN W. HOLLIS, M.D. Series edited by Dr. Victor Cox Pedersen, A.M. 8vo, 319 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia. Price, $1.00 net.

DIE PHYSIOLOGISCHEN UND PATHOLOGISCHEN BEZIEHUNGEN DER WEIBLICHEN SEXUALORGANE ZUM TRACTUS INTESTINALIS UND BESONDERS ZUM MAGEN. Von Dr. EDWIN KEHRER. 8vo, 315 pages, paper. S. Karger, Berlin.

EIGHTEENTH REPORT (FIFTH BIENNIAL) OF THE STATE BOARD OF HEALTH OF THE STATE OF NEW HAMPSHIRE FOR TWO YEARS ENDING NOVEMBER 1, 1904. 8vo, 270 pages, illustrated, muslin.

MANUAL OF PSYCHIATRY. By J. ROGUES DE FURSAC, M.D. Translated by A. J. ROSANOFF, M.D. Edited by Joseph Collins, M.D. 8vo, 352 pages, muslin. John Wiley & Sons, New York. Price, $2.50.

THE URINE AND FECES IN DIAGNOSIS. By OTTO HENSEL, Ph.G., M.D., and RICHARD WEIL, A.M., M.D. 8vo, 334 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia.

THE PRACTICAL MEDICINE SERIES OF YEAR BOOKS. Edited by GUSTAVUS P. HEAD, M.D. Vol. 1. GENERAL MEDICINE. Edited by FRANK BILLINGS, M.S., M.D., and J. H. SALISBURY, M.D. Vol. 2. GENERAL SURGERY. Edited by JOHN B. MURPHY, M.D. 8vo, 347 and 545 pages, illustrated, muslin. The Year Book Publishers, Chicago. Price, $1.00 per volume.

THE VERMIFORM APPENDIX AND ITS DISEASES. By Dr. HOWARD A. KELLY, A.B., and Dr. E. HURDON. 4to, 827 pages, illustrated, muslin. W. B. Saunders & Company, Philadelphia. Price, $10.00 net.

THE AMERICAN YEAR-BOOK OF MEDICINE AND SURGERY FOR 1905. By various authors. Edited by GEORGE M. GOULD, A.M., M.D. Volume 1, GENERAL MEDICINE. Volume 2, GENERAL SURGERY. 8vo, pp. 701 and 696, illustrated, muslin. W. B. Saunders & Company, Philadelphia. Price, $3.00 per volume.

THE PHYSICAL CULTURE LIFE. By H. IRVING HANCOCK. 12mo, 229 pages, illustrated, muslin. G. P. Putnam's Sons, New York.

PROGRESSIVE MEDICINE. Vol. VII., No. 1, Whole No. 25. March 1, 1905. Edited by Dr. HOBART AMORY HARE. 8vo, 298 pages, illustrated. Lea Brothers & Company, Philadelphia. Price, $6.00 per annum.

ANNUAL REPORTS OF THE DEPARTMENT OF AGRICULTURE FOR THE FISCAL YEAR ENDING JUNE 30, 1904. 8vo, 560 pages, muslin.

THE INTESTINAL CATARRHS. Being a clinical study of Colitis, Appendicitis, and their Allies; with a special new section on Sprue. By EDWARD BLAKE, M.D. Second Edition. 8vo, 356 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, $2.00 net.

ELEMENTS OF APPLIED MICROSCOPY. A Text-Book for Beginners. By CHARLES-EDWARD AMORY WINSLOW. 12mo, 183 pages, illustrated, muslin. John Wiley & Sons, New York. Price, $1.50.

GYNECOLOGY—MEDICAL AND SURGICAL OUTLINES FOR STUDENTS AND PRACTITIONERS. By HENRY J. GARRIGUES, A.M., M.D. 8vo, 461 pages, illustrated, muslin. J. B. Lippincott Co., Philadelphia.

SAUNDERS' QUESTION-COMPENDS. ESSENTIALS OF THE PRACTICE OF MEDICINE. By WILLIAM R. WILLIAMS, A.M., M.D. 12mo, 460 pages, muslin. W. B. Saunders & Company, Philadelphia. Price, $1.75 net.

RECHERCHES CLINIQUES ET THERAPEUTIQUES SUR L'EPILEPSIE, L'HYSTERIE, ET L'IDIOTIE. Par BOURNEVILLE. Vol. XXIV. 8vo, 346 pages, illustrated, paper. Felix Alcan, Paris.

ZEITSCHRIFT FÜR KREBSFORSCHUNG. Herausgegeben vom Komitee für Krebsforschung zu Berlin. Redigiert von Prof. Dr. D. v. HANSEMANN und Prof. Dr. GEORGE MEYER. Dritter Band. Erstes Heft. 8vo, 193 pages, illustrated, paper. August Hirschwald, Berlin.

Surgical Suggestions.

A Modified Bassini Operation.—Polya has found the following a satisfactory modification of the Bassini technique. In incising the external oblique, the lower flap is left quite wide and is turned down out of the way, as usual. The rectus sheath is slit up 1 cm. from its outer edge and reflected, this flap being then drawn over the inner part of the junction of conjoined tendon and Poupart's ligament by the sutures used to close the posterior wall of the canal. The cord is stripped of most of its veins, and the upper edge of the external oblique is sutured to Poupart's ligament. The cord is then placed in a new canal formed by bringing over it the lower wide flap of the external oblique, the upper edge of which is made fast to the part of the external oblique above the line of incision. The author has treated forty-seven cases by this method and considers that it offers greater security against recurrence than the usual plan of procedure.—*Zentralblatt f. Chirurg.*

Colles' Fracture.—Painful manipulations are not necessary to determine the presence of a Colles' fracture. The styloid process of the radius normally occupies a level lower (nearer the fingers) than that of the ulna. When the tip of the radius styloid has receded as far as or beyond the level of the ulna styloid, as determined with the thumb and fore-finger applied, respectively, to each, a fracture of the radius is present. On the other hand, a Colles' fracture occasionally occurs, without any of the external signs being present. An *x*-ray examination, conducted both laterally and sagitally, will demonstrate it.—*Massachusetts Medical Journal.*

Venereal Warts.—Rohrer says that while it is probable that these excrescences are not contagious the question is not yet definitely settled. The use of a dusting powder of calomel and bismuth will generally cure the growths when few and small, or one of the caustics in common use may be applied. Where they are multiple removal with curved scissors under local anesthesia and touching the base with carbolic acid or the cautery is necessary.—*American Journal of the Medical Sciences.*

Varicose Veins.—Favel recommends the following procedure in those patients in whom the saphenous vein is easily visible. With a curved needle a strong silk ligature is carried under the vessel. The point of the needle is reinserted into the opening of exit and is carried under the skin so as to emerge at the original point of entrance. The vein now lies encircled by a ligature of which both ends pass through the same opening in the skin. The thread is tightly knotted and the ends cut short so that the knot is drawn under the skin.—*Correspondenzblatt f. Schweizer Aerzte.*

Compound Fractures.—Lawbaugh, whose practice is in a mining district where such injuries are very common, says that the guiding principles in the treatment of compound fractures are: Thorough cleansing and rigid asepsis, drainage and careful immobilization, which will enable the surgeon to save limbs which at first sight seemed hopelessly lost. There is never an immediate necessity for amputation in cases in which there is sufficient circulation to sustain the parts and sufficient tissue to preserve a useful limb. Only in the case of the most severe crushing can amputation take the place of the conservative though tedious prospect of saving treatment.—*Journal of the Michigan State Medical Society.*

Spinal Cocainization.—Deloup uses a plain 4 per cent. solution of cocaine made with sterile water and heated to the boiling point at the time of the operation. Based on an experience of a little over 100 cases, he believes that the following conclusions are justified: (1) That the method is as safe as, if not safer, than general anesthesia. (2) That we may safely employ up to half a grain of cocaine without fear of toxic effects. (3) That shock, when present, is decidedly less than that of general anesthesia. (4) That it is attended with less danger of annoying sequelæ and symptoms. (5) That it can be relied on for prolonged operative procedures.—*New Orleans Medical and Surgical Journal.*

Indications for Vaginal Hysterectomy.—Vaginal hysterectomy may be resorted to in cases of small fibroma, of painful or incurable metritis, and exceptionally in inceptive epithelioma of the cervix in corpulent and aged women. On the other hand, it should be resorted to in cases of inversion and of prolapse when it is found desirable to remove the uterus, and it is absolutely indicated in cases of extensive, virulently septic periuterine lesions which persistently get worse and which colpotomy appears insufficient to cure, in cases of puerperal infection which do not improve under ordinary means of treatment, and in subacute pelvic peritonitis propagating itself toward the abdominal cavity.—*Faure in British Gynecological Journal.*

The Treatment of Club Foot.—B. E. McKenzie offers the following conclusions: (1) The ideal time for active treatment by the surgeon is early in the second year. (2) Deformity of the foot *per se* should be fully corrected; afterward the relation of the foot to the leg. (3) Cutting other than that of a subcutaneous section of the tendons and fascia is seldom or never required. Manipulative replacement and retention by fixed dressings sufficient. (4) After-treatment: A properly applied and properly constructed leather-lined boot. (5) Removal of the contramembered and harmful. (6) Operations in young persons interferes with normal development of foot. (7) In persons under fifteen years of age congenital club foot may be so perfectly cured as to give practically perfection of form and function. (8) In adults perfection of form may be secured. Function is somewhat impaired. (9) The time required for active surgical treatment need not be more than three months. (10) Age is no serious bar to treatment.—*American Journal of Orthopedic Surgery.*

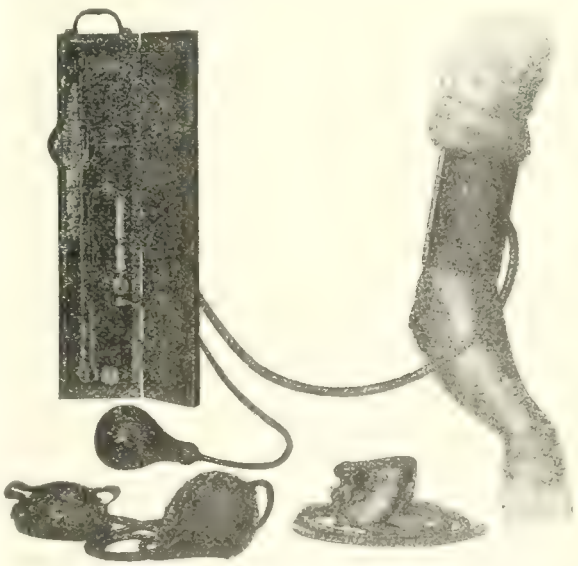
Ectopic Gestation.—Ladinski considers the following as positive signs: (1) Enlarged uterus. (2) Bleeding from the uterus, the blood being dark and grumous in character, differing from bright menstrual blood with its peculiar odor, and from the clotted blood and bits of tissue resulting from an abortion. (3) Distension of a part, or of the whole tube, the mass being peculiarly elastic, sensitive and movable. No other condition, unless it be a hematosalpinx, is so characterized. (4) Paroxysmal pain is always present as a significant sign. (5) Amenorrhea is invariably present. Among the negative signs are: (1) Absence of intrauterine pregnancy. (2) In tubal pregnancy, before a rupture of the tube, there are no changes in temperature more than observed in normal, intrauterine gestation.—*Clinical Review.*

New Instruments.

A PORTABLE SPYGMOMANOMETER.

By ALLAN McLANE HAMILTON, M.D., F.R.S.E.,
NEW YORK.

I HAVE had constructed an instrument which I believe is free from some of the objections of other alleged portable spygmomanometers, and which contains additions that I think will be found useful.



As the jointed manometer tube of the Cook and Janeway instruments is not only liable to error, but the joint is easily broken, thus losing some of the mercury, I have adopted a straight capillary tube, 40 centimeters long, with a trap and ascending tube, terminating in a brass *T*, and a three-way stopcock, the whole being placed in a strong box, 48 cm. high, 11 cm. wide and 5½ cm. deep.

The following three additions, not found in other instruments, will prove serviceable to those engaged in office and bedside investigation:

1. A pliable armlet or leg-band, consisting of a stout canvas strap, of sufficient width, which is reinforced by bands of steel; and where, instead of straps or hooks and eyes its ends may be united; or it may be reduced in size, by rings which fit over a row of what are known as "lace hooks."

2. A foot-bellows (B or C), which enables the operator to have his hands free; although, if preferred, a Politzer bag (A) or other hand air-compressor may be used.

3. A magnifying glass, so adjusted that the markings on the millimeter scale may become more legible, and more quickly read.

The apparatus is made by Messrs. Charles E. Dressler & Bro., 143-145 East Twenty-third street, New York City.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 25, 1905:

	Cases.	Deaths.
Measles	379	9
Diphtheria and Croup	294	38
Scarlet Fever	258	13
Smallpox	.....	.....
Chickenpox	180	.....
Tuberculosis	576	198
Typhoid Fever	19	6
Cerebrospinal Meningitis	167	85
Typhus Fever	.....	.....
Yellow Fever	.....	.....
Cholera	.....	.....
Totals	1,873	349

Interstitial Emphysema of the Lung.—M. J. Andrieu cites this case. The patient, a boy of two years, was brought to the hospital suffering with whooping cough. Within eleven days symptoms of bronchopneumonia developed. Dyspnea continues to increase, until death supervened on the seventeenth day after the patient's entrance to the hospital. At autopsy, the thorax was found to be dilated to the maximum, the diaphragm being pressed back. On the anterior and external surface, the lungs showed glistening spots that were easily recognized as being sub-pleural zones filled with air. In the two bases were little islands of bronchopneumonia. Over the mediastinum here and there, the same appearance was noted as over the lungs. The neck and thorax did not show similar infiltration. There were no lesions of other organs. The pathogenesis of this case of interstitial emphysema seemed to be as follows: Bronchopneumonia, compensatory pulmonary emphysema, rupture of an alveolus by the spasms of coughing due perhaps to the whooping cough, perhaps to the bronchopneumonia, the passage of air into the cellular tissue of the lung from which it penetrated as far as the visceral pleura, and into the cellular tissue of the mediastinum. The diagnosis of this complication had not been made before death. It was especially noticeable that the crepitant râle with large bubbles was not heard—a sign which Laënnec considered pathognomonic of interstitial emphysema of the lung.—*Bulletins et Mémoires de la Société Anatomique de Paris,* November, 1904.

Peroxide of Zinc in the Treatment of Varicose Ulcers.—De Beurmann and Tanon advocate the use of peroxide of zinc in the treatment of varicose ulcers. On its contact with organic liquids, it gives up oxygen which is a logical reason for its use in these lesions. The writers have employed it in different forms, such as powder and various pomades, until after many trials, they find the following formula best suited for these cases: Peroxide of zinc, 20 grammes; light vaseline, 100 grammes. With this mixture they cover the entire surface of the ulcer, after first washing it thoroughly with hydrogen peroxide. Over the pomade is applied a dressing of sterilized gauze. The entire application remains in place for from three to six days without being touched, according as the ulcer is more or less infected. In all of their cases the writers have obtained a complete disappearance of infection, a granulation of the base, and a cicatrization earlier than that brought about by other topical applications. When this improvement once begins it is rarely arrested. All leg ulcers are treated by the writers in this manner, and all have done well. They rapidly cease to suppurate, they have no disagreeable odor, and the patients can often walk a little without increasing the duration of the treatment.—*Revue Française de Médecine et de Chirurgie,* February 6, 1905.

Chronic Alcoholism in a Child with Kidney Lesions.—Guido Berghinz calls our attention to the fact that chronic alcoholism is not very uncommon in young children among nations where the drinking of alcoholic liquors is a daily family habit. The author has observed marked psychic excitation and persistent insomnia in children of two and three years of age, as a result of stimulants, and nocturnal eneuresis and nervous excitation in a child of seven from their daily use. He gives at length the case of a child of five years, who had been in the habit of taking aquavita several times a day, who came to the hospital in Rome with much dyspnea, gastric disturbances and universal edema, insatiable thirst and scanty urine, containing albumin and casts. This child called continually for aquavita to relieve his sufferings. After death the kidneys showed marked congestion, increase of connective tissue, with periarteritis and hemorrhages. There was hydrothorax and beginning sclerosis of the liver, with hypertrophy of the heart. There was an entire absence of a history of any other cause for these conditions other than the constant use of alcohol.—*Rivista di Clinica Pediatrica,* January, 1905.

Throat Complications in Typhoid.—F. J. Quinlan gives an elaborate résumé of the litlerature of this condition, and says that in case of obstructive lesions supervening in the larynx, tracheotomy offers many advantages over intubation in that the air current can be tapped by the former operation below the obstruction and the danger of forcing fragments of cartillage into the trachea is overcome; again, the tube may rupture an abscess and flood the respiratory tract with pus which (if not causing imminent danger) may provoke a septic pneumonia at a later day. A laryngitis occurring during the course of typhoid fever must always modify our prognosis. Continued hoarseness with slight dyspnea should at once demand an inspection of the larynx and trachea. A faulty movement of the laryngeal muscles should require internal local medication. Marked dyspnea should at once call for operative surgical interference.—*The Laryngoscope.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended March 25, 1905:

THE TREATMENT OF PYELITIS.*

By HOWARD A. KELLY, M.D.,
BALTIMORE, MD.

I SHALL endeavor to show from a personal experience extending over some sixteen years that pyelitis is an affection of the utmost importance to both physician and surgeon, and that in one of its most important phases, namely, its earlier stages, it is still rarely recognized, or, when found, is often thought worthy of but little attention because it is not immediately provocative of serious symptoms.

It is always interesting and sometimes helpful to take account of nature's method in dealing with a disease. A pyelitis of recent origin which is let alone often gets well spontaneously by the natural process of irrigation as the urine sweeps the infecting organisms down through the renal pelvis and the ureter into the bladder. This kind of a cure can only take place where the passages are well open. If there is an obstruction at any point causing a damming up of the urine, the pyelitis is almost sure to linger in a chronic form.

Many cases of pyelitis remain for long periods *in statu quo*. Again, other cases grow worse and worse until they end in a high grade of pyelonephritis or the kidney becomes converted into a veritable abscess sack.

A pseudo cure may take place by the closure of the sack, when the abscess may either persist or may rupture into the bowel, into the pleura, into the loin, into the groin, or even into the peritoneum.

In addressing a general audience of physicians upon the treatment of pyelitis, let me at the very outset emphasize the importance of a careful investigation of the particular cause in each case, as the mainspring of any rational plan of treatment.

It is not within my province just now to discuss the question of etiology at large; I desire, however, to point out a few of those causes which must be borne in mind in order to make the simpler plans of treatment effective. The removal of the contributing cause in many cases suffices to cure the trouble, and even if it does not cure, it often helps a great deal by lessening the grade of the infection. The treatment of the cause is then almost always a necessary antecedent to the treatment of the pyelitis, which often persists obstinately as long as the cause continues. It is alone unnecessary to consider the cause in carrying out the treatment where the cause has been of a transient nature, as, for example, in the case of an acute fever, a furuncle, or a typhoid fever, which has left a pyelitis in its trail. One of my patients, for example, had had typhoid fever thirty years previous to my treating her for a pyelitis in which the infecting organism was the bacillus typhosus; she recovered rapidly under irrigations of the kidney.

Some pyelitides depend for their source upon a gastrointestinal disturbance such as an obstipation or a catarrh. Instances of this sort are not infrequent in children, and the relief of the exciting cause of the trouble often does much towards relieving the pyelitis.

Even sucklings have been affected, and the disease has been known to advance so far that a nephrotomy or a nephrectomy has been found necessary in children of tender years. Aside from the treatment of such intestinal disorders as exist, urotropin and salol have been found valuable drugs in children.

Again, some pyelitides are lit up by the presence of a small or a large stone in the pelvis of the kidney, and this possibility must always be borne in mind. To detect a stone, either use wax-tipped renal catheters to secure a scratch mark, or the *x*-ray, or both, as mutually confirmatory or exclusive; upon removing such a gross cause the attendant pyelitis may disappear spontaneously.

Such was the case of Miss S., who came under my care in 1894. She had a right pyelitis, so diagnosed by Czerny of Heidelberg in June, 1890. A cystoscopic examination showed the right ureteral orifice red and injected, and the urine from that side contained some pus and bacteria. The right kidney was washed out eighteen times. She did not improve after a time under these irrigations, but, on the contrary, the separated urine contained even more pus. One day some little black particles escaped through the catheter, and these on examination proved to be scales of a calculus! A nephrotomy was then done and the calculus removed, when she recovered and the urine became entirely free from pus. The interesting point in connection with this case is the fact that the pyelitis after a time was aggravated by the treatments; this was manifestly owing to the presence of the foreign body.

Again, a not infrequent cause of a pyelitis is the unsuspected presence of a hydronephrosis of low grade, or the retention of a little urine in the pelvis of a kidney, not as yet distended. I have discovered many such cases in women who have had vague pains in one side of the abdomen and variously diagnosed as nervous, neuralgic or intestinal. When the pain is on the right side, I have repeatedly seen women belonging in this category from whom the vermiform appendix, the right uterine tube, and the right ovary, had been removed without, of course, the slightest benefit. There is no difficulty in tracing the source of the pain to the kidney by using the method of introducing a renal catheter as far as the renal pelvis and then injecting enough fluid to make it tense; in this way an attack of pain is brought on, which the patient at once recognizes is, or is not of the same character, and in the same place, as that from which she has been suffering. I constantly have such cases on hand, and have made demonstrations of this character repeatedly to physicians from all parts of the country for years past. It is these often baggy pelves which are most likely to catch a low-grade inflammation through a colon bacillus infection, when for any reason the general

*Read before the Medical Association of the Greater City of New York, March 13, 1905.

health becomes depressed, or in the case of a focus of suppuration elsewhere, such as a carbuncle or a furuncle. Such a patient with an attack of grippe is almost sure to have a pyelitis afterwards.

An instance of a distended pelvis in which a pyelitis became evident and threatening in the course of an attack of influenza, was that of Mrs. G., the wife of a prominent physician. She had been feeling unusually well when she was seized with febrile disturbance, with aching and soreness in body and limbs and headache followed by a marked chill. The temperature then rose to 103° F., and there was soreness all over the abdomen, especially in the epigastrium. On the second day there were two more chills, and three to four on the third day. There was no nausea or vomiting; the bowels were constipated. There was nothing to attract attention to the urinary organs except the increased amount of urine passed. The urine, however, became turbid and flocculent; it contained some whitish sediment, albumin, pus cells, and a few red blood corpuscles.

Just before I examined her she had several attacks of severe pain in the left side of the abdomen. I catheterized the left ureter February 27, 1897, and drew off 53 c.c. of a pale watery fluid in 6 minutes and 10 seconds. The last 2 or 3 c.c. consisted of a thick white sediment which dripped slowly from the end of the catheter. This single evacuation by the catheter gave entire relief, although some pus persisted in the urine. She had another attack in the following August, and on March 1 of the following year I injected 25 c.c. into the kidney, which produced severe pain exactly in the spot where the cramps had been. Following this injection I drew off 40 c.c. with less sediment than before. March 4 6 c.c. were drawn off. Complete recovery followed these treatments until March 31, 1898, when she was six weeks pregnant. She was in a wretched, depressed state of health, and was only relieved by the evacuation of the uterus. Since that time, now six years ago, she has had excellent health.

The note above made relative to the discharge of the thick sediment from the pelvis of the kidney at the end of the catheterization is most important, as it shows the true value of the evacuation and the irrigation treatments by the renal catheter. In many instances, especially where the renal pelvis is dilated, this débris is left behind to perpetuate infection indefinitely. It is easy to see how, in this way, a single treatment might give great or even entire relief, as in a case which came into my hands some years ago in consultation with Dr. Norment of Baltimore. I passed a renal catheter up into the left kidney and at once drew off about 30 c.c. of very turbid, purulent urine. The patient, who had been wretched for a long time, was so completely relieved that she refused any further examinations or treatments.

I might here also refer to the case of a Mrs. B., a patient over fifty years of age, from whose large right dilated kidney Dr. Halsted had removed a calculus. After recovery from this operation he referred her to me for the treatment of the residual pyelitis. I found that there was no secretion whatever from the left kidney, which was either absent or permanently silent, while the right hydronephrotic kidney was secreting from 2,250 to 2,400 c.c. of a pale milky urine containing abundant pus and colon bacilli. I was unable to relieve her completely of this infection, but for about two years I continued to irrigate the right kidney at intervals of a few weeks with solutions of boric acid, nitrate of silver and weak formalin. Following such treatments she was always much improved and able to return home to her somewhat arduous social duties at the National Capital. The constant reduction of the inflammation kept down the infection and kept her alive in spite of the greatly crippled kidney. After two years she died suddenly while traveling abroad.

I might add here, relative to pyelitis in displaced kidneys, that it is best as a rule to clear up the renal infection before suspending the kidney. If an infected kidney is suspended, the wound in the side may break down and a fistula will be the result.

Another class of pyelitides somewhat akin to this last group, to which I wish to direct urgent attention, are those due to a cystitis, often mild in character, affecting the base of the bladder and causing stricture of the vesical orifice of the ureter. Such a stricture causes more or less stasis of urine above, and this, associated with the ever-present vesical infection, offers all the conditions for an ascending pyelitis, lacking the mere accident of the presence of the germ.

Mrs. F. was a patient of this kind, sent me by Dr. F. M. Hicks of Texas. She had a mild vesical infection and a peculiar pain low down in the pelvis on the left side. The infection improved under local treatments, but the discomfort continued until one day while examining the bladder I saw a peculiar swelling as large as the end of the finger in the act of elongating and pushing down across the lumen of the speculum; this was followed by a retraction. During the elongation, when the swelling was at a maximum, a little stream of water was ejected from a minute orifice near the apex. This enlargement proved to be a ureter whose orifice had evidently become stenosed by an inflammatory process affecting the mucous margins alone. Upon entering one of the sharp points of a pair of scissors into the orifice and slitting it open, there was an immediate gush of urine and entire relief of the symptoms. I do not know whether there was an actual infection of the kidney in this case, but all the conditions existed in the retained urine and the adjacent infected vesical mucosa.

A case of a pyelitis depending on a cystitis was that of Mrs. B., seen November, 1901, who had an intense cystitis (colon bacillus) with a deep injection of the trigonum, especially about the left ureteral orifice, which was inflamed and bled on the slightest touch. She had been complaining for about four years. My first step was to drain the bladder through a vaginal incision, at the same time curetting the inflamed surface. The bladder recovered rapidly under this treatment, and the fistula was closed; the treatment of a persisting right renal infection was then continued by catheterization of the kidney and the injection of from 25 to 30 c.c. of a 1 to 1,000 solution of a nitrate of silver into the pelvis. She received in this way seventeen treatments in all; the disease disappeared, she made a perfect recovery, and remains well to this day.

Again, a pyelitis sometimes originates in this way: An adherent ovarian or a fibroid tumor, which has been pressing upon the ureter and damming back the urine, is removed; then, in the course of the convalescence, there is some febrile disturbance, and before long the crippled kidney catches an infection.

Such cases must come not infrequently into the hands of gynecologists. My colleague, Dr. W. W. Russell, had one in my service at the Johns Hopkins Hospital, in which he removed a large ovarian cyst everywhere extensively adherent. The pressure on the right ureter at the pelvic brim had caused a dilatation of the ureter above the brim to the size of the thumb, while the kidney and pelvis formed a large hydronephrotic sac. The bladder was torn in the enucleation and sutured, and for this reason a drainage catheter was inserted through the urethra. Over two weeks after the operation there was a chill,

marked elevation of temperature, and an ascending infection was found with a large, tender mass in the right side. Dr. G. L. Hunner catheterized the ureter, drew off 280 c.c. of thick pus, and washed out the kidney; he continued these treatments for three weeks, when the patient went home free from fever, feeling well, but with some pus still in the urine. She was seen a year later in perfect health.

A case of my own, Mrs. McC., aged forty-four, gave me a great surprise. She came under my care for a large parovarian cyst. The urine was clear on entrance and contained no pus. In about ten days after the cystectomy the temperature went up to 101° F.; a week later it was almost 104° F., and the urine was cloudy and full of pus. I did a right nephrotomy, letting out a large quantity of pus and removing large renal calculi whose presence had never been suspected.

I have in many instances seen extensive, dense strictures of the lower end of the ureter associated with tuberculosis of the kidney. In some of these the larger size ureteral catheters which I introduced, say 2½ to 2¾ mm. in diameter, could be pushed in only with great difficulty, and after the introduction, the catheter was held in the bite of the stricture as if in a vise. In such cases there is often associated with the tuberculosis a secondary invasion by one of the pyogenic organisms, a condition to which Albarran has called especial attention. The treatment is, of course, always nephrectomy, if the condition of the other side permits. Of tuberculous cases, however, I do not wish to speak at length at present.

I have never seen but one bad case of gonorrheal infection of the ureter, and that was in 1894. The ureter and renal pelvis above the stricture held 150 c.c. of milky urine full of pus. I gave this patient, in all, forty treatments, injecting solutions of boric acid, nitrate of silver 1 to 200, and bichloride of mercury as strong as 1 to 16,000. Under these treatments all infection was cleared up, and by using successively larger catheters, up to 5 mm. in diameter, the stricture was so far dilated that the amount of retained urine was reduced to 90 c.c., with a complete symptomatic recovery.

A pyelitis may also be caused by a vermiform appendix adherent over the ureter, compressing it and supplying the source of the infection.

I saw a case of this sort through the courtesy of Dr. McCoy, of Paterson, N. J. I was operating at the Paterson Hospital for a large fibroid tumor. After the removal of the uterus, I followed my routine custom of examining the appendix, and found it plastered down over the ureter, which was obstructed above it and led up to a pyonephrotic kidney. The kidney was successfully removed at a later date by Dr. McCoy.

It is obvious that removal of the cause in all of these conditions is a necessary antecedent to the cure of the disease.

We have at our command the following plans of treatment of a pyelitis:

Expectant treatment, with rest, the use of diluents and drugs, such as urotropin and salol.

The local treatment of a cystitis, especially those forms adjacent to a ureteral orifice.

Incision or dilatation of a stricture of a ureteral orifice.

Catheterization of the ureter and renal pelvis.

Irrigation of the ureter and renal pelvis.

Distention of the renal pelvis.

Instillations into the renal pelvis.

Permanent catheterization of the renal pelvis for some hours or days.

Nephrotomy (nephrolithotomy).

Nephrostomy for more or less permanent drainage through the side.

Nephrectomy in the advanced cases of pyelonephritis or pyelonephrosus.

An acute pyelitis arising in the course of febrile affection should be treated for the most part expectantly with rest, the ingestion of fluids, and the use of urotropin. If the pyelitis becomes severe, I would do a nephrotomy and drain the kidney.

Urotropin is the most valuable remedy we have today; it is also useful in preventing the disease where previous experience has shown that we might expect an attack, as for an example in a patient with an acute fever with a dilated kidney. It is of most service I believe in recent cases of colon bacillus infection.

In the direct local treatment of the disease we have at our command the following aggressive and precious methods: First, the catheterization of the ureter, which may serve the purpose, as in a case cited above, of emptying a lot of urine full of pus from the pelvis of the kidney, and so giving immediate and entire relief. In the second place, catheters of various sizes and metal catheters which I have used as high as 5 mm. in diameter may be used to dilate a ureteral stricture, so giving free vent to the urine and serving to cure the disease by natural drainage. In the third place, the pelvis of the kidney may be catheterized every two or three days for the purpose of irrigation, running through the kidney a liter or more of a bland, or a mild antiseptic fluid. As a rule, I use a boracic acid solution or nitrate of silver 1 to 1,500 or 1 to 1,000 or stronger. In the fourth place a few c.c. of a nitrate of silver solution as strong as 1 to 200 or even 1 to 100 may be thrown into the pelvis of the kidney and left there by the withdrawal of the catheter (instillation). In the fifth place, a nephrostomy may be done, draining the kidney through its dorsum in the loin, and in order to keep the ureter open for a few days, the permanent catheterization of the ureter may be added to this. The catheter introduced in this way through the ureter up into the pelvis of the kidney drains it *per vias naturales.* Albarran closed a fistula in this manner which had previously proved rebellious to treatment. In the worst cases, in which the opposite kidney is competent to do all the work, a nephrectomy must be done.

The treatment of a pyelitis must, I find by experience, often be modified by complicating conditions. Let me for example cite one or two illustrative cases.

Miss C., a trained nurse, aged 37, came to me through the kindness of Dr. P. H. Ingalls, of Hartford, Conn., in 1896. I removed a large left pyelonephrotic kidney, and demonstrated a mild colon bacillus pyelitis in the remaining kidney. In February, 1900, I removed both uterine tubes for tuberculosis together with the vermiform appendix which was covered with tubercles. During the convalescence from the pelvic operation, the grade of infection of the renal pelvis became such that large quantities of thick purulent urine were discharged through the bladder, so fetid that it was impossible for a nurse to remain in the room with the urine exposed in an open vessel. This extreme and apparently hopeless condition was so far improved by irrigations of the kidney that she was able to return to her work, which she continued for four years, when she died of a pneumonia.

Another interesting case was that of Miss P., aged 52, who had an extensive tuberculosis of the left kidney and ureter with such an intense distressing cystitis that she was completely bedridden, crying

and moaning day and night, one of the most wretched and pitiable patients I have ever seen.

She had lost all control of the bladder, and the urethra was intensely inflamed. The cystoscopic examination showed an intense widespread ulcerative cystitis and the vesical walls were covered here and there with pus and clots of blood. In addition to the tuberculous left kidney, the right kidney was infected with a colon bacillus pyelitis. I removed the left kidney and ureter, and drained the bladder both suprapubically and by the vagina; this brought such complete relief that I was able at last to treat the right kidney by nitrate of silver irrigations, with the result of giving absolute and entire relief and removing the infection, so that there was but a faint growth. For about a year past she has been in perfect health and able to resume all the responsibilities of housekeeping in city and country.

Let me, in concluding, again emphasize the importance of the mild pyelitides to the profession at large, as an almost unknown affection, and yet one that is very common and most important. It is my own conviction that these mild pyelitides are at the present moment the most important subject in the realm of urology, for two reasons. First, because of serious consequences possibly following a persistent infection, which is like a train of powder, burning slowly and leading up to a mine situated at an unknown distance, liable, therefore, to explode at any moment with disastrous consequences. Second, because timely aid and right methods will almost always bring relief and obviate the dangerous sequelæ. This subject appeals to me much as though, as a gynecologist, I were enabled to take up afresh the subject of pyosalpinx, and declare that, instead of directing attention to the great sealed uterine tubes distended with pus, I had found a way to recognize this disease in its incipiency, while as yet it amounted to nothing more than a mild catarrh, curable by mild measures and obviating the need for a radical operation. With what eager interest the entire gynecological world would investigate such an important announcement!

And yet here we have an organ of far greater value to the economy than either or both of the uterine tubes; we have long recognized the advanced gross destructive lesions called pyelonephritis and pyelonephrosis; and now, if clinical histories show that these are often but the end-products of a mild infection which is amenable to treatment, how urgent the need of investigating and relieving it. The general indifference to mild pyelitides, while great attention is bestowed on the large pus kidneys, is much as though an internal specialist were to devote great attention to the crumpled and thickened heart valves of advanced heart disease, while refusing to pay any attention at all to an endocarditis in its earlier stages, because it is so mild. *Verbum sapienti satis est!* Let me apply to these cases the well-worn metaphor of the sword of Damocles. Personally, I have too often seen the sword fall on the unsuspecting neck not to heed the warning given by pus and microorganisms in the urine in every case, whether from a cystitis or from a pyelitis.

Let me conclude this brief sketch by offering a few practical deductions.

1. It is important to take cognizance of a pyelitis of any grade whatever, as it may, at any time, become a menace to the functional value of the kidney, or even to life itself.

2. The severer grades of the affection are often the sequelæ of a milder pyelitis of long standing.

3. The first step in the investigation is to determine the extent of the affection by estimating the amount of pus in the urine and the relative number of organisms.

4. It is important to determine the cause of the infection, which is often of a mechanical nature, and therefore easily relieved.

5. By removing the cause, the disease may either be cured, or be so far benefited that a subsequent complete relief by means of local treatments is easily brought about.

6. The milder forms are best treated by rest, abundant water and urotropin.

7. If there is not a speedy improvement, the next simplest plan of treatment is the catheterization of the kidney every two to four days for the purpose of evacuation, distention of the pelvis, irrigation, and instillation. Boric acid and nitrate of silver are the best drugs in this connection.

8. Improvement should be measured by the disappearance of pus from the urine and the diminution in the organisms, taking say three platinum loops as the measure in conveying the infected urine to the agar.

9. A patient improved, but not cured (complete absence of bacteria), should be watched in the intervals of treatment, and guarded with especial care in case of any intercurrent disease. Should such a disease supervene, urotropin is a good prophylactic.

10. The severer forms of the disease may be treated by irrigation, which often brings great temporary relief. As a rule, however, the kidney must be opened and drained; if it has been extensively diseased, it should be removed.

ETIOLOGY OF ENLARGED PROSTATE.*

By L. BOLTON BANGS, M.D.,
NEW YORK.
FORMERLY PROFESSOR OF GENITO-URINARY SURGERY IN THE UNIVERSITY AND BELLEVUE MEDICAL SCHOOL; CONSULTING SURGEON TO ST. LUKE'S AND BELLEVUE HOSPITALS, ETC.

The subject of enlargement, or so-called "hypertrophy," of the prostate still occupies a very important place in the medical mind, not only because of the prevalence of the malady, but also because of the impetus given to its surgical treatment by the clinical and experimental observations of the last five or eight years. Surgical methods have been perfected, and the death rate has gradually been reduced, but the latter is yet an important factor when considering what should be done to a given case. Therefore, notwithstanding the improvements in technique and the valuable results of the operation, any attack upon the prostate is still to be regarded as an important operative procedure, not to be undertaken lightly nor without due consideration of other conditions of the patient who is to be subjected to operative procedure. Several years ago, in attempting to account for enlargement of the prostate, I asked myself the question, "Why should the health of such a large proportion of men begin to be undermined by a harassing, and sometimes alarming, series of symptoms, at a period of life when they ought to be the most comfortable and capable of their greatest and best work?" There must be some cause for this very wide in its application. Moreover, it seemed to me that if we could get a reasonable theory of this cause, prophylactic deductions might be made which, in the future, would prevent the evolution of the pathological conditions necessitating surgical intervention, and thus add another chapter to the glorious volume of preventive medicine. With this in view, I beg leave to present briefly what I have been forced to believe is the underlying cause

* Read at the Ninety-ninth annual meeting of the Medical Society of the State of New York, February 1, 1905.

of the tissue changes in the prostate gland. Long ago John Hunter advanced the theory that prostatic enlargement was of inflammatory origin. His experiments upon the lower animals were corroborative of this, but, in the course of time, his views were entirely overlooked, and various other theories, some of them ingenious and plausible, were advanced. But none of them satisfied the scientific mind. Virchow, in his noted work upon *Krankhafte Geschwülste,* in 1863, reasserted the belief that the process was an inflammatory one, beginning, as a rule, in the glandular parts of the gland, and extending thence to the stroma. This view was not supported by any extensive histological investigations, and did not receive the attention which it deserved. But, recently, *i.e.* within a few years, more positive scientific work has again brought to the front the inflammatory origin of enlargement of the prostate. The French view, that enlargement of the prostate is a senile process, due to general arteriosclerosis, and that even when it occurs in the comparatively youthful, it is a state of "pre-senility," has, in my opinion, been disproven, and does not need to be considered. The inflammatory theory appears to be the one which accounts for the onset of this malady, which explains the changes in the gland, and which has the most and strongest evidence in support of it. This view accords so with my own clinical observation that I give it my adherence.

It has been shown that the enlargement is histologically a proliferation (in many cases to an immoderate degree) of the constituent elements of the prostate, the various forms which the gland assumes being due to the location and degree of the proliferation. According to Ciechanowski's opinion, the different forms of prostatic hypertrophy are difficult to differentiate. They are one and the same thing. His investigations point to the conclusion that any division of hypertrophy of the prostate into different forms and subdivisions is forced and unjustified, and that the so-called (pseudo- or fibro-) adenomata of the prostate are due to accumulations within the acini of the gland. The order of events, according to his view, is as follows: A catarrhal process occurs in the acini, producing active proliferation, desquamation, and degeneration of the epithelium; at the same time a productive change takes place in the stroma, which compresses the excretory ducts of the acini, narrowing or obliterating them. The latter prevents the escape of the contents, the secretions accumulate within the acini, and the lobules enlarge. Occasionally a suppurative process is added, abundant leucocytes being added to the excretion of the gland. The enlargement of the lobules, due to increase of connective tissue elements, is quicker and of higher grade if the excretory ducts are numerous and nearer the obstacle. The enlargement of the lobules is also greater according to the extent and intensity of the endoglandular process always present. This view of Ciechanowski has been confirmed and supplemented by Greene and Brooks, in their article on "The Nature of Prostatic Hypertrophy," and which is well worthy of careful study. The invidious nature of this inflammatory process is unquestioned. It may be latent for years, with no symptoms to attract the attention of the subject of it, and the data upon which to base a diagnosis of prostatitis have entirely passed from the patient's memory. According to histological examinations, the point of origin seems to be in the prostatic urethra, extending thence along the gland ducts from the urethra towards the periphery of the prostate, the round-celled infiltration being most marked in the vicinity of the verumontanum. The latter statement is, in my opinion, of importance. It accords so with the clinical observations which I have made that it seems to me worthy of some consideration. In examining persons who have come to me in adolescence or early manhood, I have been struck with the excess of sensibility appreciated when the location of the verumontanum is touched during the process of the examination, and with the hyperemia of this little organ when viewed through the urethroscope. This I have found most marked in masturbators and in those who have practiced coitus reservatus or coitus interruptus, and in those who have committed sexual excesses, even if the sexual act has been done normally. This led to the question, "May this be the starting point of chronic prostatitis?" Although I have been unable to verify this statement by any personal histological investigations, the statement of Ciechanowski in respect to the preponderance of inflammatory elements in the neighborhood of this subdivision of the prostate is, to my mind, of considerable importance. The anatomy and physiology of the prostate are peculiar and distinct from any other organ of the body. It is subject to what I might term voluntary engorgement, and which, induced frequently, according to the temperament of the individual, easily renders it liable to infection and to the tissue changes which we call inflammation. Hyperemia of this organ stimulates the sexual nerve centers, which in turn react upon the prostate, and sexual activity becomes aggravated. Thus, in some individuals, sexual craving becomes excessive, and no amount of good sense or philosophy can fully control it. The brain and prostate reciprocate in their effect upon each other, and the subsequent tissue changes in the latter take place in response to excessive nerve stimuli. From the age of puberty onward this is liable to occur, and the man who escapes without some damage to his prostate may well rejoice.

Manson Moullin states, "It is certain, from the facts of human, as well as comparative anatomy, that the normal development of the prostate is dependent upon that of the testes and vasa deferentia. If the testes are removed in early life the prostate does not grow. If the vasa deferentia is not developed upon one side of the body, the prostate upon that side fails too, even though the corresponding testis is present. There are exceptions, but not sufficient to prevent the acceptance of the general principle. It is almost as certain that enlargement depends upon some influence exerted by the same structures. The relative frequency with which enlargement occurs diminishes as the activity of the testis fails."

In my opinion, hypertrophy of the prostate is not a senile disease. It begins in early manhood. It is present when least suspected. The changes in the prostate are coincident with the active life of the testes and vasa deferentia. The late phenomena of urinary difficulty and obstruction are often preceded by symptoms of irritation of the prostate and neck of the bladder, which are purely congestive in their nature, but are the "shadows of coming events," the prodromes of the conditions which eventually produce the more or less severe grades of insufficiency of the bladder. These phenomena do not appear in any intensity until after the age of 45 or 50, but their beginning is at the time of life when the individual is in the active exercise of his sexual functions, and when all the structures of his body are at their highest capabilities. Such considerations as these long ago led me to appreciate that the mode of life of the individuals presenting themselves with enlarged prostate had much to do with the origin of their malady. This further led to care-

ful, persistent, and tactful cross-questioning of each individual, with the object of developing his sexual life from boyhood onward. The material for this study has not been limited to persons of any one class of society. All grades, the refined and the vulgar, the trained mind and the untrained, have furnished the material. A careful analysis of three hundred such histories of persons with unmistakable enlargement, who have been under my personal observation, shows that over 85 per cent. of these persons were subjects of abnormal or unphysiological sexual indulgences, which were excessive in degree and continued for years. In the 15 per cent. remaining, in which no history of sexual aberration was present, the primary prostatic congestion was apparently due to a derangement of the portal circulation, due to sedentary life or to excessive eating and drinking. My claim is that the overactive and unphysiological—especially the latter—exercise of the prostate precedes, finally excites, and then prolongs the inflammatory irritation, which eventuates in the recognized tissue changes. To substantiate and make clear this claim, let me give you types from my recorded cases. A lad, either from the teaching of companions or from natural tendency, and without the restraint of proper and sensible instruction, becomes a masturbator. He repeats the act frequently or infrequently, according to his temperament or opportunity. But, no matter, even infrequence is too often, and before long he is in a state of chronic sexual erythism. The prostate participates in each erection, it becomes congested in response to each erotic thought, and, sooner or later, its vessels remain dilated. Even at this stage evidences of disturbance of function and of tissue change are present. The act of urination may be increased in frequency, and may be lame or hesitating, and in the urine, if examined carefully, may be found floculi or shreds of epithelium from the prostatic urethra. The whole urethra is hypersensitive, the prostatic portion especially so, and the location of the verumontanum will be found to be soft and exquisitively sensitive. At this time the lad's attention is arrested, his conscience aroused, and his innate manhood asserts itself. He stops the unnatural habit, and some of the local hyperemia disappears. But his mind is not at rest sexually. He is alive to every erotic suggestion. Partial erections are excited by trivial things. His prostate remains in a state of erythism, and lame urination persists. Involuntary seminal emissions now disturb him. Each one is like a prick of conscience to him; he would rather walk the floor all night than have one. He now falls a ready victim to "remedial institutions" and quacks of all kinds. In the meantime he has fallen in with a person of the opposite sex who is responsive to him, and a sort of virtuous calf-love begins. He seeks her society constantly, remains with her by the hour if he can, and all the time in a state of partial or complete erection. They go on from step to step and excite each other wofully. He caresses and fondles her. She permits everything but the sexual act, and to him the effects are disastrous. From some of them he never recovers. His symptoms are now aggravated and increased. Besides the lame or hesitating urination and the floculi of epithelium which have multiplied, he has shorter intervals between the acts of urination, and, in some individuals, even at this period of life, I have seen a few drops of blood follow the urine. He is irascible, morbid, and at times in a state bordering on sexual frenzy. Sexual intercourse now seems to him the only relief and to be the cure-all of his miseries. If the prostate be now examined, a distinct increase in volume will be appreciated. The organ has lost the sense of firmness and vigor which are characteristic of its normal state, and which can be distinctly appreciated by the skilled finger. Even soft pressure upon the lobes will provoke a peculiar sensation, as if the glans penis were being pounded or hammered, and the slightest touch upon the location of the verumontanum will cause an intense sensation of scalding or burning. In some cases an outcry of pain will be caused by the gentlest manipulation. From this point onwards there is a divergence, according to the moral status of the individual. Let us follow the lad who, restrained by good morals, timidity, or want of opportunity, does not fornicate. He is among those who come to you in after life with prostatic disease and say: "Doctor, I do not understand it. I never had any venereal disease. I never even had intercourse until I was married, and now, look at me." The doctor himself does not understand the etiology, unless he has been able to follow such cases as I am now describing to you. But when, by questioning, you remind him of his youth, and of that period in his development when, by repeated excitation, whether he had previously been a masturbator or not, overactivity of his prostate had been caused, and, finally, symptoms had resulted, he does come to understand, with you, the relation of cause and effect. The indulgences which I am describing are persisted in, but, college or business life intervening, they are forcibly restrained in number and duration, and the boy gets freedom from the acuteness of his symptoms. If now he remains continent in thought and deed, the congestion gradually subsides, the swelling of the prostate reduces, and even lame urination disappears. But, unfortunately, the reverse is too often the case. A habit easily gratified has been formed. In vacation hours, or hours of social relaxation, it is gratified, at least enough to maintain the prostatic hyperemia. Now he really becomes engaged to be married, and happy is the one of these subjects whose circumstances permit speedy marriage! For during the period of engagement (or "keeping company") many of the foregoing circumstances, with their accompanying physical conditions, are renewed. He is now married, and the presupposition would be that this physiological state would gradually relieve the hyperemia and cure his symptoms. And so it does for many who, through good advice or by the application of their own common sense, arrive at a suitable sexual hygiene. But even many of these go through a period of feeble erection, premature ejaculation, and urethral irritability before sexual equilibrium is attained. But let us follow the man whose marital relations are either excessive, or unnatural, or both. Excessive in the sense of too frequent intercourse is usually the rule, and not the exception, in early married life, and if the individual starts in with a hyperemic prostate, it requires no argument to show that the latter is easily maintained and augmented. Normally, the intervals between the acts of coitus should be long enough for the dilated vessels to recontract, for the nervous system to recover from the reaction which follows such a demand upon the vital forces, and for the sense of general well-being to be maintained. This healthy interval will vary with the individual, *i.e.* according to his age, temperament, nervous susceptibility and his recuperative power at the time. Suppose the man whom we are now considering does not wish children. Or his wife, being one of those women who, having learned that "only fools bear children," or one who, thinking only of the responsibilities, and not the joys of motherhood, requires him "to do something to prevent conception." In response to

these requirements he establishes the custom of "withdrawal," or "pulling out," "coitus reservatus," or "coitus interruptus." Coitus is, therefore, unphysiological, never satisfactory, and he is led to prolong the act. He is in an habitual state of hanker. Hence the act is frequently repeated, and always under the same circumstances, and presently the evidence of damage to his prostate makes its appearance. For, in response to increase of function, there is increased nutrition, and only a moderate additional irritation is required to produce the changes in the tissues. This begins insidiously, advances according to the activity and persistency of the cause, and according to the vitality of the individual, but may not manifest itself by symptoms for several years. There is another and large class of cases to which reference should be made, because in these persons we may easily overlook the important factor of sexual hyperemia. In these gonorrheal infection pervades the history. Satisfied by the history of gonorrhea, which they frankly give, we are apt to forget questions which would develop their sexual habits before and after the acquisition of gonorrhea. After analyzing a number of cases of prostatic hypertrophy with reference to this point, I have come to the conclusion that, while gonorrheal infection may be a factor in some cases in the production of the enlargement, there must be some other additional cause. A very large proportion of the cases of gonorrhea are ephemeral. The disease is one of the conditions of "sowing wild oats." Many men never have it more than once, and, as a result of this experience, resolutely live hygienic and temperate lives, which enables the infection, with all its accompanying or complicating symptoms, to disappear entirely. The evidence is not strong enough to convince me that gonorrhea alone is the primary cause of hypertrophy of the prostate. Then again, hypertrophy of the prostate occurs in men who have never had gonorrhea, whose character, honesty, and sincerity enable one to believe they are telling the truth when they deny gonorrheal infection. Belief in their statements can easily be corroborated by the confidence and evident sincerity with which they tell of the other intimate details of their sexual lives. Therefore, I am satisfied that something else besides gonorrhea is necessary (certainly in a large proportion of the cases) to induce enlargement of the prostate. I believe that if a man, even if he has been infected by gonorrhea, will lead a normal, physiological existence, especially as relates to his sexual apparatus, he will never have that condition, with all its attendant and consecutive phenomena, which we call enlargement of the prostate. From the foregoing a few simple prophylactic rules, which seem reasonable and logical, may be deduced: (1) Sexuel instruction in boyhood; (2) chastity in youth; (3) sexual self-restraint in early manhood, and (4) physiological sexual relations in the married state.

MICROSCOPICAL EXAMINATION OF THE FASTING STOMACH CONTENTS AND ITS DIAGNOSTIC VALUE.

By WILLIAM ACKERMAN, M.D.,
MILWAUKEE, WIS.,
AND
LOUIS M. GOMPERTZ, M.D.,
NEW HAVEN, CONN.
FORMERLY ASSISTANTS IN THE GASTROINTESTINAL POLYCLINIC OF DR. PAUL COHNHEIM, BERLIN.

In endeavoring to obtain a correct and early diagnosis of diseases of the stomach the practitioner usually devotes a great deal of attention to the chemical analysis of the stomach contents, but is inclined to disregard the more important microscopical examination. Many times when the chemical examination fails to be of any value, the microscope, in skillful hands, proves a powerful aid to diagnosis, and frequently this examination discloses the first evidence of a beginning stagnation, when macroscopically the fasting stomach contents may have the appearance of normal gastric juice.

When the diagnosis is in any way obscure, it should be a routine practice to make a thorough microscopical examination of the contents of the fasting stomach. The importance and accuracy of this method cannot be overestimated, and in Cohnheim's Polyclinic it has frequently enabled us to arrive at an early diagnosis, which could not have been made otherwise. On account of its importance, and owing to the fact that relatively little has been written on this subject, we deem it opportune to describe the different microscopical findings and demonstrate their value in the differential diagnosis of gastric diseases.

Such examination is especially indicated when the slightest suspicion exists of gastrosuccorrhea, stagnation—whether due to benign or malignant obstruction—or ulcerating cancer not causing stenosis. In these cases one glance through the microscope oftentimes gives more information than could be obtained by any other method of examination at our disposal. It sometimes happens, however, that patients are sent from distant parts, and do not come with the stomach in a fasting condition. If they are unable to come for a second consultation, we are, at such times, obliged to withdraw and examine the contents of the non-fasting stomach. The same disadvantage exists when vomitus or a test breakfast is sent for examination.

The technique is simple. In this clinic stomach contents are extracted by the expression method only. For the fasting stomach we use a No. 9 or 10 soft rubber tube with two large lateral fenestræ, one a little higher than the other, and situated on opposite sides. We never find it necessary to use an aspirating bulb. If only a very small amount of contents is present, it can be withdrawn with Fenton Turck's brush or by the expression method, and the smaller particles which adhere to the inner sides of the tube can be obtained by blowing through it. Whenever we suspect the presence of infusoria the tube and receptacle for the stomach contents are heated to body temperature in order to prolong the activity of the protozoa.

After the withdrawal of the fasting stomach contents we carefully examine the material macroscopically as to its general appearance, quantity and odor. The fluid withdrawn may either have the appearance of normal gastric juice, or may be changed by the admixture of stagnating food remnants, mucus, bile, blood, pus, tiny pieces of mucosa or tumor particles, which, if present in large quantities, can be recognized with the naked eye. A small amount of fluid (5 c.c. to 15 c.c.) can be considered normal, as this may be either mucus and saliva swallowed during the night, regurgitated bile, or, possibly, gastric secretion due to increased glandular activity resulting from irritation of the stomach tube. The constant presence, however, of 20 c.c. or more of pure gastric juice must be regarded as abnormal. In cases of stagnation, the peculiar characteristic odor of gastric juice is sometimes changed by the presence of butyric and acetic acid, or by putrefactive processes. The well-known rancid odor of butyric acid is easily recognized, while putrefactive processes give rise to a fetid odor.

As already mentioned, we may find normally sev-

eral cubic centimeters of fluid in the fasting stomach. If this is only swallowed mucus or sputum, we have a fluid of slightly *alkaline reaction,* containing stringy, tenacious mucus, which, if coming from the trachea or bronchi, occurs in small clumps, pigmented with tiny dust particles. This pigment is composed of iron or coal dust, and at times hematin may be present.

For a careful examination, the stomach contents are spread upon a white plate, and if, with the naked eye, suspicious particles can be distinguished, these should be selected for examination. This is important, as it may enable us to determine more quickly the microscopical changes, and obviate the necessity of repeated examinations. After this general survey we proceed to the microscopical examination, with which we determine points of vital importance. The microscopical field is carefully studied for the presence of those abnormal constituents which, from the clinical history of the case, we expect to find. If nothing abnormal is discovered at the first examination several slides should be made.

If the material is composed of swallowed mucus and sputum we see microscopically numerous alveolar cells. They are elliptical in shape, about twice the size of a leucocyte, and have indistinct nuclei, which at times cannot be seen without the addition of acetic acid. The protoplasm is granular and sometimes contains small fat globules. We also find many unchanged pavement epithelial cells, which come from the mouth, pharynx or esophagus; unchanged leucocytes, and, at times, homogeneous bodies similar to fat drops, having their origin in the sputum, the so-called myelin bodies.

On the other hand, if the small amount of expressed fluid is composed of swallowed mucus, plus gastric juice, the microscopical findings are vastly different from the above. Free nuclei of leucocytes and of epithelial cells, isolated yeast cells, bacteria, and, possibly, spiral or snail-like bodies are found. The spiral bodies and the free nuclei were first described by Jaworski, and through the investigations of Tellering, confirmed by Cohnheim, we now know them to be myelin bodies, acted upon by the HCl, and of no pathological significance. Free nuclei of leucocytes and of epithelial cells are also due to the peptic action of gastric juice, and *their existence is positive evidence of the presence of HCl and pepsin, and we are thus enabled to determine* microscopically *the presence of gastric secretion.* Therefore, when we find myelin, alveolar and unchanged epithelial cells, we know that they had their origin from the bronchi or upper digestive tract, and remained unchanged in the stomach on account of the absence of HCl and pepsin. On the other hand, if we find free nuclei of leucocytes, epithelial cells and snail-like bodies in the fasting stomach, then we are positive of the existence of HCl and pepsin.

Thus we have two distinct characteristic microscopical pictures of the findings in the contents of the fasting stomach, and a chemical examination is not necessary to prove the absence or presence of gastric secretion.

Having briefly described the microscopical findings which can be regarded as normal, we will now consider the pathological conditions found in the fasting stomach contents, and in order to present this subject in the most concise form possible, we submit the following tabulation:

A.—Without Stagnation. (1) With HCl, free nuclei, spirals of snail-like bodies, striated mucus. (2) Without HCl, (*a*) leucocytes and epithelial cells, which are unchanged; (*b*) pus, blood, mucus, and, possibly, infusoria and amebæ.

B.—With Stagnation. (1) With HCl, sarcinæ, yeast cells, food remnants. (2) Without HCl (with lactic acid), Oppler-Boas bacilli, yeast; absence of sarcinæ.

A.—(1) This comprises stomach contents which are free from stagnation, but contain HCl. Here the characteristic free nuclei of leucocytes, occurring in groups, and known as Jaworski's kernels, are present. When the medium is strongly acid these kernels are extremely shiny, while if only a slight acidity is present their appearance is dull and they are larger in size.

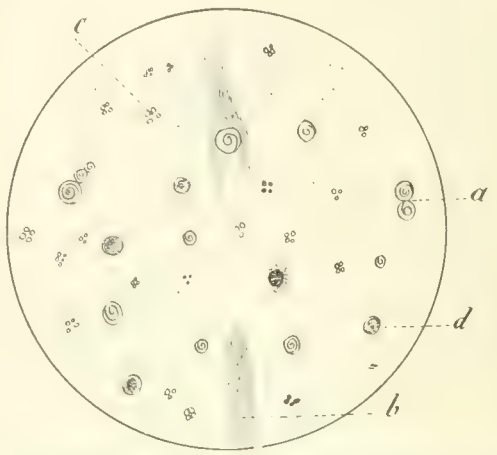

Fig. 1.—*a*, Spiral bodies; *b*, striated mucus; *c*, free nuclei of leucocytes; *d*, free nuclei of epithelial cells.

It has been demonstrated by Jaworski that gastric juice (HCl + ferments) will act upon pus cells and produce these kernels; also that HCl alone will give the same result, the change, however, requiring a longer time. Free nuclei of epithelial cells may come from the cylindrical or pavement variety, and under favorable conditions may at times be seen. The pavement epithelial cells are large, and consequently their nuclei are far apart, but owing to the shape and smaller size of the cylindrical epithelium, the nuclei of these cells are closer together. If the protoplasm has disappeared, and the remaining nuclei of the cells are few in number and far apart, it is evidence that they are derived from the pavement epithelium, while if they are numerous, closer together, and appear in rows, then they have their origin from the cylindrical epithelium. According to Jaworski, the presence of very many leucocytes, the number of which can be determined from their remaining nuclei, indicates an anatomical change of the mucosa, as Sachs demonstrated that in catarrhal conditions the leucocytes wander through the epithelial cells of the mucosa. Striated mucus and spiral bodies, already described, are also found.

In cases where these findings are present, and the quantity of fluid upon repeated examinations exceeds 20 c.c., we are justified in believing that there is an overstimulation of the glandular elements. This condition is known as a continual hypersecretion, or gastrosuccorrhea. The fluid in these cases should always be examined microscopically, as the presence of sarcinæ, yeast cells in chains, food remnants, such as starch granules, muscle fibers, etc., prove an accompanying stagnation.

A.—(2) Under this division HCl and food remnants are absent from the stomach contents. Two subdivisions are noted: (a) Contents containing epithelial cells and leucocytes which are unchanged, and (b) cases in which the unchanged leucocytes and epithelial cells are present, but, in addition, pus, blood, and, possibly, infusoria and amebæ are found.

(a) When a large amount of mucus is present a diagnosis of gastritis is often made without a microscopical examination. This is absolutely wrong. A diagnosis of gastritis should never be made on account of the presence of mucus without first determining its origin, and this is only possible by a microscopical examination. As stated before, if pavement epithelial cells are present in large numbers, the mucus comes from the upper digestive tract. Mucus from the bronchi and lungs is characterized by the presence of myelin drops and alveolar cells, while the occurrence of a great many cylindrical epithelial cells is positive evidence of its origin from the gastric mucosa. If the source of the mucus can be traced to the gastric mucosa, and there is no HCl present, we are then justified in making the diagnosis of gastritis anacida.

(b) Neoplasms, though most frequently found at the gastric orifices, do not arise from them, as was formerly supposed, but generally take their origin from the smaller curvature, and then radiate either towards the pylorus, cardia, or fundus. This can be best illustrated by the following diagram, for which we are indebted to Dr. Cohnheim.

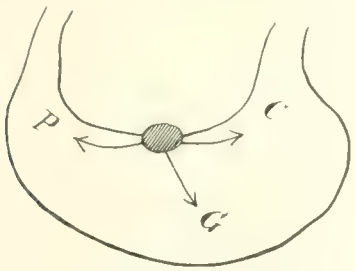

Fig. 2.—*P*, pylorus; *C*, cardia; *G*, greater curvature.

The reason the smaller curvature is most frequently the primary seat of carcinoma is undoubtedly due to the fact that this is the part most exposed to mechanical, chemical, and thermal irritation from the ingesta. If a cancer has its origin at the smaller curvature and radiates towards (*P*) the pylorus, an early stagnation usually results, and the findings in this condition will be described later. A carcinoma growing in the direction of (*C*) the cardia is, as a rule, not difficult of diagnosis, as in this condition the patient experiences difficulty in swallowing, and a resistance to the passage of the gastric bougie is met at about 40 cm. from the incisor teeth.

If, however, the carcinoma is situated on the smaller curvature, between the cardia and pylorus, and does not affect either one of these orifices, but radiates towards (*G*) the greater curvature, a condition exists which is extremely difficult to diagnose. Usually in these cases the subjective symptoms, as well as the physical and chemical examination, point to a gastritis anacida, as in both of these diseases (carcinoma and anacid gastritis) there is no stagnation, and the test breakfast shows an absence or diminution of HCl, pepsin, and rennet. We are, therefore, utterly in the dark as to the true nature of the disease, and here the microscope is oftentimes of inestimable value in giving a clear picture of the pathological processes taking place in the stomach. If, with these conditions, the microscopical examination shows the constant presence of pus and blood, and their origin can be excluded as coming from an acute phlegmonous gastritis, or purulent inflammation from other parts (mouth, tonsils, bronchi, etc.), a positive and early diagnosis of ulcerating interosteal carcinoma can be made long before a tumor is palpable or characteristic symptoms are present.

Single leucocytes are found normally in the stomach, more especially, though, in the different forms of gastritis. They are only pathognomonic of cancer when accompanied by blood and appear in compact form. They may occur either in small clumps or thick, tenacious mucus. The appearance of pus

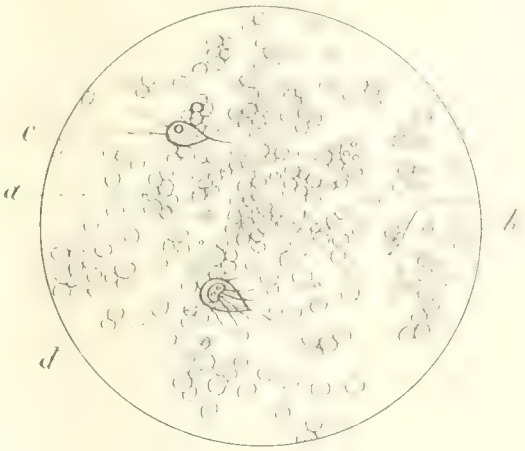

Fig. 3.—*a*, Pus cells; *b*, pavement epithelium; *c*, trichomonas; *d*, megastoma.

in fetid, putrid contents of the fasting stomach, together with caseous masses, is of much greater diagnostic importance than when the contents are non-fetid; but the former occurs very much later, and usually after a tumor is palpable. Therefore the presence of pus in non-fetid contents affords, as a rule, a relatively early diagnosis.

In all suspected cases, especially with progressive emaciation, anorexia, gastric distress, etc., without stagnation, but with achylia gastrica, we should endeavor to procure some of the fasting stomach contents. Usually but very little is obtainable, perhaps only a few cubic centimeters, but this is sufficient for a microscopical examination. These are the cases in which infusoria and amebæ are likely to occur, and therefore the stomach tube and receptacle should be warmed.

Much importance has been attributed by many investigators to the protozoa found in the intestinal tract, but very little attention has been paid to the occurrence of these organisms in the stomach. Here two varieties of infusoria have been found, namely, *Trichomonas hominis* and *Megastoma entericum*. Under proper precautions, these infusoria are readily recognized by their motility and peculiar characteristic shapes. *Trichomonas hominis* is elliptical in shape, similar to an almond kernel, is from 8 to 12 microns in length and has one caudal and two or three ciliary head processes, the latter being in rapid motion. *Megastoma entericum* is pear-shaped and a little larger than the Trichomonas. It may be distinguished by its two tail threads and six long flagellæ, which serve as propellers. On the broader extremity are two cavities, which resemble suction cups. Infusoria of stagnating water may be confounded with the above, and therefore great care should be taken in making the microscopical preparation to avoid the possibility of regarding these infusoria as coming from the stomach, which would lead to a faulty diagnosis.

For the development of infusoria, four conditions are necessary: (1) absence of HCl; (2) presence of alkaline reaction; (3) absence of stagnation; (4) the existence of pouches or deep folds in the gastric mucosa. Therefore infusoria are always found with pus and blood, and these conditions are present only in cases of interosteal carcinoma, not attacking the pylorus. As already stated, when pus and blood are constantly found in the fasting stomach, the diag-

nosis of an ulcerative process is justifiable. This could certainly be substantiated in no better way than by the finding of infusoria. *Trichomonas hominis* is frequently found in carious teeth and *Magastoma entericum* in the intestine, but the presence of either in the stomach is evidence of extra-pyloric carcinoma, as they have never been observed unless this condition existed.[1]

Strube was the first to demonstrate the presence of infusoria in the stomach. Hensen, Zabel and Ullman have also contributed to the literature on this subject, but Cohnheim deserves the credit of having given the true diagnostic value to these protozoa, and in his publications on this subject he emphatically states that he is far from believing that these parasites can be considered as the cause of carcinoma, but that their presence is pathognomonic of a carcinoma not affecting the motility of the stomach. Not being disturbed by an acid reaction, they are able to live and propagate in the pouches of the ulcerated mucosa. In a stomach with simple atrophy, the pouches are missing, while when stagnation occurs, whether it be due to benign or malignant obstruction, an acid medium results. If the obstruction is benign, an acid medium exists due to hydrochloric acid, while if it be malignant in character, lactic acid is present owing to fermentative processes. Under these conditions there is, necessarily, an absence of the infusoria, as they are killed by acids, and thrive and multiply only in alkaline media. Infusoria die very quickly at room temperature and when exposed to light, and unless special efforts are made to keep them at body temperature and to exclude the light they rapidly become encysted. They can then be recognized by the oval form and homogeneous character of the cyst. The conditions governing the growth of infusoria also favor the propagation of amebæ, and consequently the two are often found together.

The finding of amebæ and infusoria is not only of extreme value as a pathognomonic sign of carcinoma, but their presence often enables the early diagnosis of this disease, as they are found long before the appearance of a tumor. The reason that so little can be found in literature on gastric infusoria is due to the fact that the practitioner usually neglects the microscopical examination of the fasting stomach's contents, and with the exception of a few authors, comparatively little effort has been made to determine their existence.

At this point tumor particles or small fragments of gastric mucosa sometimes found in the stomach contents may appropriately be mentioned. Boas was the first to utilize such specimens for diagnostic purposes, and is of the opinion that we are often enabled to ascertain, by a microscopical examination of these bits of mucosa, the exact morbid anatomical conditions existing. Many others (Cohnheim, Hayem, Einhorn, Leuk, Martius, Hari, Hemmeter) have since made a study of these pieces of tissue. It is, of course, of the greatest diagnostic value to find specific elements of carcinoma, but they rarely aid in making an early diagnosis, as they are usually found after the disease is well established, and very frequently the shreds of mucosa obtained are necrotic and therefore unfit for histological purposes.

B.—We will now consider the second division, namely, gastric secretion plus stagnation.

By stagnation is meant the finding in the fasting stomach of remnants of food taken one or more days before, and this indicates a stenosis of the pylorus. This stenosis may be caused by benign or malignant growths, spasmodic contraction of the pylorus due to fissure, erosion or ulcer; to a cicatrix of an old ulcer, to perigastritis or to mechanical factors, as tumors of adjacent organs, causing pressure from without, all of which may affect the pylorus. As benign obstruction of the pylorus occurs with hydrochloric acid, and malignant obstruction without it, there are, therefore, two distinct subdivisions: (1) Stagnation occurring with HCl and (2) Stagnation without HCl.

B.—(1) Stagnation with the presence of HCl. This is indicative of either benign obstruction or of an ulcus carcinomatosum of the pylorus. Very frequently on withdrawing the contents of the fasting stomach, it is presumed that there exists a simple gastrosuccorrhea, as with the naked eye no food-remnants can be detected, but the microscope discloses the first evidence of stagnation. According to Strauss, in order to have a true gastrosuccorrhea, no sarcinæ or yeast cells in chains must be found, and further, the fermentation test must be negative. In our opinion, the fermentation test is unnecessary, because if sarcinæ, yeast cells in chains, food-remnants, such as starch granules, muscle fibers, fat globules or crystals and plant cells are found in the fasting stomach contents, it cannot be regarded as a pure uncomplicated case of gastrosuccorrhea. The presence of these substances is a positive sign that there is an appreciable disturbance of the motility of the stomach combined with gastrosuccorrhea.

In cases of hyperacidity and hypersecretion, muscle fibers are partially digested, and as a consequence the striæ have more or less disappeared, but amylaceous food will not be changed. Yeast cells, single, or in pairs, are usually found in the stomach contents, but in cases of stagnation they occur in chains, and when the obstruction is of a benign nature, are usually accomplished by sarcinæ.

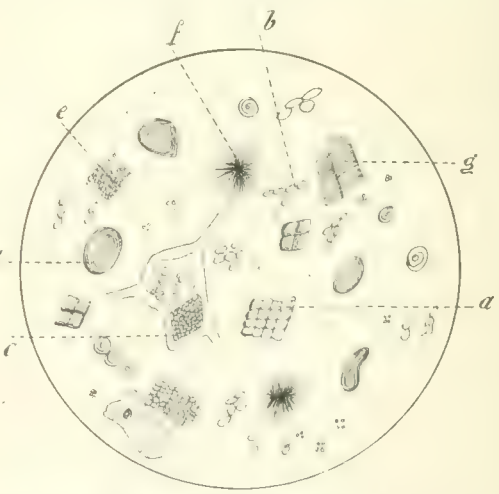

Fig. 4.—*a*, Sarcinæ; *b* yeast cells, *c*, plant cells; *d*, starch granule; *e*, degenerated sarcinæ. *f*, fat crystals; *g*, muscle fiber.

The latter are never found unless the stomach contents contain hydrochloric acid, and their presence is proof of benign obstruction of the pylorus with one exception, namely, in cases where a carcinoma develops upon the base of a previously existing ulcer. This is commonly known as ulcus carcinomatosum.

[1] Since the writing of this article, Rosenfeld, in the *Deutsche med. Wochenschrift*, 1904, No. 47, reports six cases in which the trichomonas was found in the fasting stomach contents. In five of these cases tumors were present, but the sixth, after 18 months' observation, presented no symptoms of carcinoma. The flagella were found only twice, and in close succession; therefore the possibility exists, as Rosenfeld suggests, that they were carried down from the carious teeth, their presence in the stomach being only temporary. However, Zabel reports a case in which the protozoa were found two years before pronounced symptoms of carcinoma developed. If Rosenfeld's case does not prove to be gastric cancer, it is the first one reported in which protozoa were found in a non-carcinomatous stomach.

In obstruction caused by spasmodic contraction of the pyloric ring due to fissure, erosion or ulcer, or in obstruction caused by the cicatrix of an old ulcer, there is a hyperchlorhydria and an abundance of sarcinæ. If the base of the ulcer undergoes a carcinomatous transformation, then there occurs a gradual diminution of the hydrochloric acid owing to atrophy of the glands, and a simultaneous decrease of sarcinæ. In the course of this disease the hyperchlorhydria soon gives way to a subacidity and with the latter we still have the presence of sarcinæ, though they are fewer in number and of a degenerated form. As the growth of the carcinoma progresses, there is a gradual decrease of the hydrochloric acid and sarcinæ, until finally there may be a total absence of both; the HCl being supplanted by lactic and other organic acids, and the sarcinæ by the Oppler-Boas bacilli.

If the transformation is a rapid one, there is a possibility of finding a few degenerated sarcinæ, together with the Oppler-Boas bacilli, in the same stomach contents. Sarcinæ are generally found in groups of four, eight or sixteen, etc., and are very seldom observed singly. In shape they resemble cotton-bales or packets and occur in two sizes—large and small. Degenerated forms, which are rounded, irregular and more or less fragmented, are also observed in cases that have been under treatment.

B.—(2) Stagnating contents containing lactic acid likewise has its characteristic constituents, and by the microscopical examination we derive as much information as can be elicited from the many chemical tests. With the exception of a slight change in the muscle fibers where hydrochloric acid is present, the examination of the food particles will not aid in differentiating one division from the other, as there is stagnation of food remnants in both divisions. Yeast cells in chains are also common to both.

The examination of the leucocytes is more satisfactory, as they are found in different stages of digestion. When hydrochloric acid and pepsin are present, the protoplasm is entirely digested, leaving nothing but the centrally grouped nuclei (Jarworski's kernels). In lactic acid fermentation, the protoplasm is granular and shrunken, but still retains a faint definite outline.

The same applies to the epithelial cells. Instead of free nuclei being found, as in the presence of HCl, they are surrounded by coarsely granular protoplasm. Spiral bodies may also be found, due to the action of lactic acid on the myelin cells.

The differentiation of these two divisions can, however, be very readily made.

The sarcinæ are so constantly found in stagnating stomach contents containing HCl, that their appearance is regarded as distinctly characteristic of benign obstruction, with the exception before noted, that of carcinomatous ulcer.

In the stagnating stomach contents containing lactic acid, the sarcinæ are supplanted by the Oppler-Boas bacilli, and these should be considered of even more diagnostic importance as indicating malignant stenosis than the finding of sarcinæ in benign obstruction.

The Oppler-Boas bacilli are unusually long and non-motile bacteria, and can be recognized by their large size and end-to-end arrangement.

The finding of the Oppler-Boas bacilli in the gastric contents is not only of importance as a diagnostic sign, but is of the greatest practical value. In pyloric carcinoma, the situation of the growth is such that it is hidden by the liver, and by the detection of these bacilli we are often enabled to make a diagnosis long before the tumor becomes large enough to be palpable. They may, therefore, serve as an indication for surgical intervention.

Oppler was the first to draw attention to the lactic acid bacilli, and their practical diagnostic value was then demonstrated by Boas, who at first

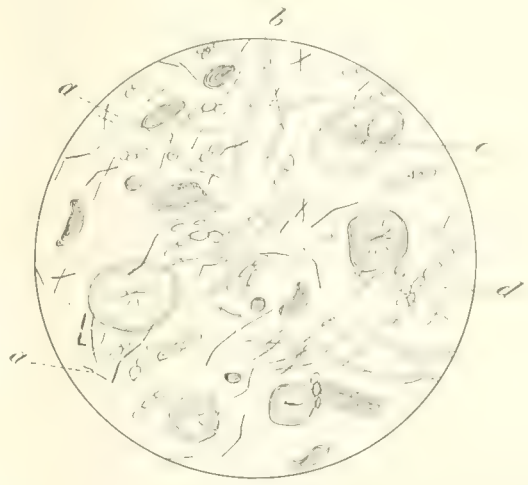

Fig. 5.—*a*, Oppler-Boas bacilli; *b*, leptothrix; *c*, potato cell; *d*, yeast cells

regarded them as pathognomonic of carcinoma. It is now known, however, that stagnation with lactic acid formation is not specific of pyloric carcinoma, but depends upon the concurrence of two factors present in this disease, namely, the absence of hydrochloric acid and the presence of stagnation. These same conditions exist in gastritis gravis or stenotic gastritis, where there is an inflammatory hypertrophy of the pars pylorica, resulting from a long-standing atrophic gastritis. Primarily, there is an atrophy of the gastric glands and as a consequence of the passage of coarse foods over the pyloric end of the stomach, a compensatory hypertrophy of the pars pylorica ensues. This gradually leads to a stagnation, and the conditions eventually become the same as in pyloric carcinoma, as in both diseases there is stagnation of food with subsequent lactic acid fermentation, and an absence of hydrochloric acid and the gastric ferments. These bacilli may also be found in carcinoma of the esophagus or cardia. In both of these affections there occurs a dilatation of the esophagus above the obstruction, in which there is an accumulation of food remnants in an alkaline medium, and the conditions are then analogous to those produced in carcinoma of the plyorus.

Another fact to be taken into consideration is that not only carcinomas of the stomach but of all other internal organs may cause an atrophy of the gastric mucosa, and if from any cause whatsover, a pyloric obstruction occurs, the Oppler-Boas bacilli are liable to be found in the stagnating stomach contents. Therefore, carcinomas of neighboring organs, by exerting pressure on the plyorus, may cause an obstruction, and as the systemic effect of the cachexia in these cases has already produced a gastric atrophy, the findings of the stomach contents will be the same as in gastric carcinomas affecting the pylorus. Thus it is evident that the findings of pyloric carcinoma, gastritis gravis, a carcinoma of a neighboring organ pressing on the pylorus and thus causing stagnation, are the same, but as the two latter conditions are so very rarely found, they need hardly be considered in differential diagnosis. According to Cohnheim, about 99 per cent. of the cases with stagnation and Oppler-Boas bacilli or lactic acid, are pyloric carcinoma, the remaining 1 per cent. being

either gastritis gravis or a carcinoma in the vicinity of the pylorus. Boas reports only three cases of gastritis gravis.

Therefore, the presence of the Oppler-Boas bacilli can be regarded as an indicator for operative procedure, and the remote possibility of a stenotic gastritis does not modify the treatment, as surgical intervention is indicated in either case. Thus, the practical diagnostic value of these bacilli is evident and their early detection may be the means of prolonging and perhaps saving many a life in a disease where the prognosis is necessarily fatal without surgical intervention.

Résumé.—1. The presence or absence of hydrochloric acid can be determined by a microscopical examination of the fasting stomach contents.

2. The origin of mucus can be determined only by a microscopical examination.

3. By the microscopical examination, mild cases of pyloric stenosis can be differentiated from simple gastrosuccorrhea.

4. Constant presence of pus, blood and possibly infusoria in the fasting stomach contents is absolute evidence of extra-pyloric carcinoma.

5. Benign obstruction can be diagnosed early by the finding of sarcinæ, yeast cells in chains, or food remnants.

6. The early diagnosis of malignant obstruction of the pylorus can be made by the finding of the Oppler-Boas bacilli.

We desire to express our thanks to Dr. Paul Cohnheim for his valuable advice and supervision of the microscopical work.

ACUTE CHOLECYSTITIS IN THE PUERPERIUM. REPORT OF TWO CASES. CHOLECYSTOTOMY. RECOVERY.

By HIRAM N. VINEBERG, M.D.,

NEW YORK.

ATTENDING ADVISORY SURGEON TO MT. SINAI HOSPITAL. VISITING GYNECOLOGIST TO ST. MARK'S HOSPITAL.

It is rather singular that so little has been written on cholecystitis in the puerperium. In looking through a number of works on obstetrics, both recent and ancient, I find the subject mentioned in only two—that of P. Müller, Bd. II, p. 918, and Schauta, *Lehrbuch der Gesammten Gynaekologie*, Leipzig, 1896, p. 631. Schauta covers the subject in six lines, and Müller in five lines. Schauta says pregnancy and the puerperium seem to favor the formation of gallstones. He quotes Thiriar, from an abstract in the *Berliner klinische Wochenschrift*, 1885, No. 48, in which it is stated that a case of cholelithiasis during pregnancy of such severity was seen that it was necessary to perform cholecystectomy, and Schauta adds that he himself had seen a case of biliary colic in the fifth month of pregnancy with such severe symptoms that he considered cholecystectomy indicated. After a careful search of the literature for the past ten years, I found the report of only four cases of cholelithiasis necessitating cholecystotomy in the puerperium (Potocki,[1] Pinard,[2] Eiermann,[3] Rose[4]), and two such cases in pregnancy (Van Engelen,[5] Doleris[6]).

During the past summer it was my good fortune to be called into consultation in two instances in which I made the diagnosis of acute cholecystitis, and the diagnoses were verified by subsequent operation. In both cases the attending physician had previously made the diagnosis of puerperal sepsis.*

Case I.—Acute Cholecystitis Nine Days After Delivery; Cholecystotomy on the Twelfth Day; Recovery.

On July 30, 1904, I was asked to see in consultation a patient in the downtown district, who had been delivered twelve days before, and who was now suffering, as the doctor thought, from puerperal sepsis. The patient was 31 years old, had been married ten years, and this was her fifth child. The labor had been normal, but took place amid unsanitary surroundings, and with as imperfect precautions to asepsis as usually obtain in such homes. The woman seemed fairly well for the first nine days, and apparently had no elevation of temperature. On the ninth day she was seized with rather severe pain in the abdomen, the temperature went up to 103°, pulse 120. She had no nausea nor vomiting. The abdominal pain and fever persisted until I saw her. At my visit I found a large and stout woman, with a heavily coated tongue and a considerably distended abdomen. Her breathing was rather short and jerky. The first impression she made was that of one suffering from acute puerperal peritonitis. On questioning her, she said that the pain was all over the abdomen, and that she had not had any movements of the bowels for two days, although several efforts had been made to move them, both by purgatives and enemata. A bimanual examination found the uterus in a normal state of involution for that period of the puerperium, and the adnexa were apparently normal. No exudates nor swellings were found in the pelvis. I extended my examination to the abdomen. It was considerably distended and fairly rigid, especially on the right side. The rigidity seemed most marked in the right hypochondrium, and here also was the greatest tenderness. By direct interrogation I learned that the pain was very severe at this point, and on further interrogation the husband stated that his wife had been subject to attacks of "cramps in the stomach" for several years, and that frequently during these attacks a ball would appear in the epigastric region, which he would rub away. As far as either husband or wife knew, these attacks were not attended or followed by jaundice. The patient showed no evidences of jaundice at the present time. I made the diagnosis of acute cholecystitis, rather to the surprise and relief of the attending physician. The patient was taken at once to Mt. Sinai Hospital, where the same night I performed cholecystotomy. The gall-bladder was very much distended, was the size of a medium-sized pear, and contained some free pus and

*Since writing this paper I have received the January, 1905, number of the *Monatschrift für Geburtshülfe und Gynäkologie*, which contains an article by Dr. Christian on Cholecystitis in the puerperium. The article embodies the report of two cases observed by the author. The first case showed symptoms on the fourth day of the puerperium, and was seen by the author on the ninth day. He made the diagnosis of acute cholecystitis on the following day. The patient recovered, palliative treatment only being employed. The second case showed symptoms eight days before labor, which set in at the usual time. The symptoms persisted after delivery and the patient made a slow recovery under palliative treatment.

dark colored bile, with numerous small stones. The temperature fell to normal on the third day after operation, and the recovery was rapid, the patient leaving the hospital on the seventeenth day. The fistula closed in about six weeks. Latterly the patient has been complaining of considerable discomfort in the epigastric region, but has not had any disitnct attacks of pain.

Case II.—Cholecystitis Ten Days After Delivery; Cholecystotomy on the Same Day; Recovery.

In October, 1904, about two months after I had seen the first case, I was requested by a physician to see a patient who was suffering, as he thought, from puerperal septic infection. He had delivered the patient, a primipara, 20 years of age, ten days before. The placenta seemed to be adherent, and the doctor had to remove it manually, otherwise the labor was normal. The puerperium seemed to have progressed normally until the morning of the day I was called, when the patient was seized with a severe chill, followed by fever and pain in the left iliac region. After a few hours the pain spread over the entire abdomen, and was most marked in the right half of the abdomen. I saw the patient at 4 P. M. She appeared to be very ill, with a dry coated tongue, a temperature of over 103°, and a pulse of 120. The abdomen was not distended, but was rather rigid, especially in the right umbilical and hypochondriac regions. There was an area of decided tenderness in the region of the gall-bladder, and it appeared to me as if I could make out an ill-defined mass in that region. On bimanual examination the uterus and adnexa did not show any abnormality, the uterus being in the usual degree of involution. There were no wounds in the vagina, and the slightly torn perineum looked healthy. I unhesitatingly made the diagnosis of acute cholecystitis, notwithstanding the fact that the patient stated positively that she never had had any attacks of pain in the epigastric or hypochondriac regions, and that she had always been healthy. There was no nausea nor vomiting, and there were no evidences of jaundice.

I had considerable difficulty in convincing the attending physician and another consultant who was present that we had to deal, not with a case of puerperal sepsis, but with an acute affection of the gall-bladder.

The patient was at once removed to Mt. Sinai Hospital, where, a few hours later, I performed cholecystotomy. The gall-bladder was very much distended, being the size of a large pear, and its walls were considerably thickened. It contained very little pus, being filled chiefly with a thick dark fluid and numerous small stones. The temperature fell to normal on the third day, but convalescence was somewhat protracted by rheumatic pains in both legs. The patient left the hospital four weeks after the operation. The fistula persisted for some weeks thereafter, but closed rather promptly after the expulsion of a small calculus.

Taking into consideration the frequency with which women suffer from gallstones,* bearing in mind the statement made by reliable authorities (Naunyn, Schauta) that pregnancy and labor favor the occurrence of biliary colic, acute cholecystitis in the puerperium ought to be a more frequent occurrence than the literature would seem to warrant. It is probable that the disease is often overlooked, or is mistaken for puerperal sepsis.

Even so able and experienced an observer as Pinard treated his case as one of puerperal sepsis for ten days before the true condition was diagnosticated by accidentally discovering a tumor mass in the right hypochondrium.

Dr. H. Huchard[8] collected twenty-two cases of biliary colic during pregnancy and the puerperium. In several of the cases the diagnosis of puerperal sepsis had been made before Huchard was called into consultation. In one case he himself had first diagnosticated puerperal peritonitis. He relates an interesting instance in which he was called, in absence of the family physician, to attend a woman in supposed labor. The woman was having severe abdominal pain, which she interpreted as labor pains. After watching the patient for some time he came to the conclusion that the so-called labor pains were the manifestations of an attack of biliary colic.

The attack of cholelithiasis during pregnancy or during the puerperium may be the first the patient has experienced, as in my second case.

Berline-Hering[9] collected fifty-one cases of biliary colic, in eleven of which the first attack occurred during pregnancy, in four the first attack followed an abortion, and in the remaining thirty-six cases the first attack followed labor in periods varying from one day to one month.

Willemin (quoted by Dreyfus-Brisac[10]) relates an instance in which a woman had an attack of biliary colic after her two labors at an interval of nine years, and another, that of a woman who had an attack after each of the four labors she passed through. These women had not experienced an attack at any other time.

In Schroeder's statistics, upon which Naunyn places the greatest reliance, as the autopsies were under the direct supervision of V. Recklinghausen, 90 per cent. of the women who had gallstones had borne children. The conclusion that must be drawn from these facts is that pregnancy favors the formation of gallstones. It does this, according to Naunyn, by interfering with the flow of bile through the ducts. He says we know that the expulsion of the bile from the common duct is materially aided by the pressure to which the liver is subjected by the movements of the diaphragm in respiration. This has been demonstrated by the experiments of Heidenhain and his pupils. In women, the corsets keep the diaphragm at rest, and in pregnancy the same result is produced, but in a different way. The absence of diaphragmatic respiration, and the exclusively costal type of breathing in women is not conducive to the flow of bile. For the production of acute cholelithiasis in addition to stagnation of the bile, it is usually conceded at the present time that some form of microorganism is necessary. The most frequent organism found is the bacillus coli.

C. A. Herter[11] quotes the statistics of W. Peterson, who, in fifty operations for gallstones, found bacteria in the bile forty-four times. In thirty-six instances the bacillus coli was found. In the constipation that usually attends the pregnant state we have a favorable condition for the migration of the bacillus coli into the gall-bladder. According to Skutsch,[12] the outbreak of an attack of biliary colic during the puerperium is to be attributed to the change of abdominal pressure, thus favoring the passage of calculi from the gall-bladder into the ducts. Is it not more likely that the outbreak of acute cholelithiasis during the puerperium is favored by the time-honored custom of not allowing the parturient woman to have a movement of the bowels during the first three days of the puerperium, and of keeping her in the dorsal position for at least the same period?

We have already noted the difficulties besetting

* Schroeder found that in all the autopsies in the Strassburg Hospital from 1880-1877, 20.6 per cent. of the female cadavers had gallstones (Naunyn).[7]

the diagnosis of acute cholecystitis in the puerperium. Some authors lay great stress upon the presence of vomiting and jaundice. Both of these symptoms were absent in my two cases. The presence of a tumor in the right hypochondrium would, of course, greatly aid in the diagnosis. But this tumor, even when present, is not easily palpated in an obese patient, with general distention of the abdomen, as in Case I. In Case II, the general rigidity of the abdomen prevented a satisfactory examination. But in both cases, after the patients had been transported to the hospital and a thorough evacuation of the bowels had been effected, a tumor mass could be definitely felt in the gall-bladder region.

In making the diagnosis in a given case, the first essential is to be able positively to exclude an infection of the genital tract. This very often is not an easy task, particularly if we are called during the first three or four days of the puerperium. What struck me especially in the first case was the short, jerky respiration. Respiration of such a character, to be caused by peritonitis, would mean a very extensive process, and this I was able to exclude. I therefore sought for another cause, and found it in the tender and painful area in the right hypochondrium.

The treatment of acute cholecystitis in the puerperium must be based on the same principles that govern that disease at other times, and need not be entered into here. It may, however, be stated that the parturient woman seems to bear surgical intervention as well as the non-parturient. The pregnant woman who enters into labor with a distended empyemic gall-bladder, does so with great peril. I vividly recall being asked to see in consultation some years ago a patient who had just passed through a normal delivery, and who within a few hours after delivery was suffering from symptoms of acute general peritonitis. Her condition was so grave as not to warrant any surgical intervention. She died about twenty-four hours after delivery. The attending physician, a careful and capable man, told me that the patient had had several attacks of biliary colic during pregnancy, but had gone through them all safely. Before labor set in he thought he could map out a distended gall-bladder. During the progress of the labor, which was normal in every respect, the patient uttered a shrill cry at the acme of a labor pain, and said she felt something give way. Delivery occurred shortly afterward, and then symptoms of violent peritonitis set in, with the result already stated. I made a vaginal examination and found the uterus and vagina in a normal condition. There can be but little doubt that during the height of a pain the gall-bladder ruptured, and its septic contents were discharged into the general peritoneal cavity. An autopsy was not permitted.

Rose[13] also reports a case of empyema of the gall-bladder, with gallstones, that ruptured during labor. In spite of operative intervention, on the second day, and drainage, the patient died on the third day from a septic infection, presumably of the peritoneum.

CONSERVATIVE TREATMENT OF PROTRACTED CASES OF ACUTE OTITIS MEDIA PURULENTA, WITH ITS COMPLICATIONS.*

By ALFRED WIENER, M.D.,
NEW YORK.

We usually expect an acute otitis media purulenta to get well in from two to three weeks. When such an otitis continues beyond this time there is something at fault which protracts the healing. That such protraction is often to be traced to etiological influences, and the constitutional condition of the patient before the attack, should be borne in mind.

During the past winter (1903 and 1904) it was my object to pursue as conservative a policy as was consistent with the strictest surgical principles in the treatment of this class of cases, and to observe and record carefully the results. I was surprised to find in what a large percentage of my cases such a policy could, under certain conditions, be followed with absolute success. In four of the cases radical interference had been advised by a second consultant, an opinion in which I must confess I also would have concurred, had I not previously planned for myself a conservative form of treatment, which, if allowed to be carried out, I thought would prove just as successful. In this I was not mistaken. I feel I owe no apology, therefore, if I put on record my experiences with this plan, at a time when we otologists are inclined to be less conservative than we should. It claims acknowledgment and trial on the part of all. To insist upon delay and not to indulge in needless surgery when the opportunity is offered of carefully watching and treating each individual case, will bring forth results which will cause astonishment. Such rational therapeutics in the hands of competent otologists will assist the reparative processes to a very great degree. I am quite ready to agree with Pyle, who says, that "as a physician, there is not one of us who would not trust to rational, conservative measures until indications were pronounced, before he would submit to surgical interference." The laity demand just as deliberate and conservative consideration. I do not wish to be understood as deprecating all radical surgical measures, but the pendulum has swung too far. Unnecessary mutilation of the human body for the sake of exploratory procedures, when more time should be taken to study our clinical ear pictures, and an attempt made to arrive at a diagnosis, is not to be encouraged.

In order to demonstrate in the most convincing manner possible the methods which I pursue, I have chosen to relate in detail the histories of selected cases of the severer type. In all, during a period of five months, there were treated in my clinic at St. Luke's Hospital, and in my private practice, 22 cases of this particular type, and, with the exception of three cases, all the patients recovered completely without any radical measures having been resorted to. These three cases were due to an acute inflammation having engrafted itself upon ears which had undergone previous inflammation, or were still the seat of a subacute form, and, therefore, offered very little power of resistance. I shall limit myself in this paper to the narration of six cases.

*Read before the Metropolitan Medical Society.

Case I.—A child four years of age was seen in consultation with Dr. Koplik. This child was just recovering from an attack or scarlet fever. It was during the third week that a spontaneous perforation had taken place in the drum of the left ear, followed by a slight discharge. At the end of the fourth week, there was a sudden rise of temperature, with vomiting, and nothing to account for this change except the ear. I was asked to see the child and we at once found sufficient in the ear to explain the change. A pale, anemic looking child, very much emaciated, and who appeared to be suffering a great deal of pain, judging from the anxious expression on its face and the constant moaning. Its temperature taken in the rectum at the time was 104°. There was just a trace of edema over the mastoid portion of the temporal bone. In regard to tenderness on pressure, it was a very difficult matter to decide this point, as the child resisted any manipulation whatever. It appeared at times, however, to be especially sensitive over the region of the antrum. Examination of the ear showed the following: The tympanic membrane was reddened, swollen, and bulging to such a degree that its distinctive marks, such as the handle of the hammer, the short process, and the sharp outline between itself and the external auditory meatus were entirely obliterated. Especially prominent was this bulging in the upper and posterior quadrant. In regard to the diagnosis, I felt reasonably sure to assume that, in addition to the purulent inflammation of the middle ear, there was also an empyema of the antrum, as both the picture on the drum and the excessive tenderness over that part of the bone demonstrated. How severely the mastoid region was involved was a question which I decided could best be solved by measures which I proposed we should follow in the treatment. We know perfectly well that high temperature in these cases can be produced by a toxemia. If this is the case, then a thorough cleansing and drainage of these parts should at once have a decided influence upon this temperature. Especially in children can such drainage be carried out. In the newly born the antrum is the only pneumatic space present in the mastoid bone, situated behind the tympanum, and, what I wish to lay special emphasis upon, at a higher level. *A cellular mastoid at this time does not exist.* These cells in the mostoid do not develop until the period between the second and third years (Bezoldt). According to Schwartze and Eyesell, these cells, when they do develop, are arranged in a typical manner radiating towards the antrum. This arrangement in the adult is seldom recognizable, partly through the formation of new osseous septa, and partly through the disappearance of those already formed. The above arrangement of these cells in the mastoids of children is a very advantageous one, as one can at once understand how materially this will assist in the drainage of this part. The treatment carried out in this case was the following:

The external auditory canal was thoroughly cleansed and an incision was made extending through the posterior superior portion of the canal, posterior superior and inferior quadrant of the drum, and the secretion carefully wiped out. This was immediately followed by a thorough politzeration and aspiration of the middle ear. More secretion appeared in the canal; was wiped away and the following dressing was now applied: A piece of strip iodoform gauze, one-half of an inch wide, dipped into a ten per cent. solution of liquor Burowii (an aqueous solution of acetate of lead and alum) was placed in the canal. An occlusive external dressing, wet with the same solution, was placed over the ear and a bandage applied. The child slept well that evening. The next day the temperature was 99° and the child was in very much better spirits. The dressing was removed, the opening in the drum probed to prevent it from closing, the middle ear politzerized, and the same dressing applied. On the third day the patient was so well that the external dressings were discontinued. For certain reasons now it was not possible to see the child daily. The mother was instructed how to carefully wash out the secretion in the external canal. For this purpose a two per cent. solution of lysol was used. I wish to say right here, this is a procedure that I am not in favor of, as I invariably, when the treatment cannot be followed out by a competent nurse, personally irrigate or cleanse such ears only with cotton wrapped probes. For seven days this child did well, when there was a sudden rise of temperature, and I was asked to see the child again. The same condition was found as on the first occasion, due this time to the fact that the incision made a week ago had entirely closed. A paracentesis was made at once and the same treatment followed out as before, but now by the attending physician. In addition, some advice was given in regard to baths, fresh air, and good, wholesome food. The child now gradually improved, and after four weeks was entirely well.

Case II.—Referred to me by Dr. Heiman. A child 16 months of age, perfectly healthy in appearance, had suffered from an attack of bronchopneumonia two months previous to the time that I first saw it. Directly after its recovery from the above attack it developed an acute otitis media purulenta. It was placed under special care, but the ear did not seem to get well. After two months' treatment, the child began to suffer with pain over the antrum and mastoid on pressure, and, in addition, began to have slight evening rises of temperature. About this time I was asked to treat the child. On examination I found a tympanic membrane bulging over its posterior superior portion and directly below this part, situated in the posterior inferior quadrant, a nipple-shaped perforation close to the margin of the drum. The drum was reddened, but did not present that angry look which we find in the more acute condition. There was distinct tenderness over the mastoid, but especially over the antrum. The secretion had a slight odor. Temperature taken at my office was 100° by the rectum. The right ear revealed a retracted tympanic membrane, and when the pharynx was examined the cause was at once evident. Obstructing it was a large mass of adenoids. The question at once arose in regard to the treatment, whether it would be wise to open the antrum in this case, or attempt to pursue a conservative policy for a few days. As there was surely no urgent reason for operative interference, I pursued the following plan. I made a large incision through the posterior superior and inferior quadrants of the tympanic membrane, including the perforation in the incision, cleaned out that ear as thoroughly as I possibly could, and then placed upon it an occlusive wet dressing with gauze drain in the canal. This treatment of thorough cleansing and wet dressing was kept up for four days in succession. The temperature now being normal I at once removed the adenoids, and within three weeks the child had entirely recovered and the ear was practically well.

Case III.—A child 13 months of age, seen with Dr. Koplik in consultation. This child was just recovering from a mild attack of scarlet fever and suddenly developed a temperature of 105°. Dr. Koplik had already convinced himself that the temperature could not be accounted for in any other

way except through the ear. This patient was extremely poorly nourished and with a most violent temper, so that only by main force was a most difficult examination made. In the canal of the right ear I found some discharge which had an extremely bad odor. The whole canal was narrowed and it was just barely possible by pushing the speculum in somewhat forcibly to get a view of the tympanic membrane. This was reddened and bulging, further I could determine nothing. The paracentesis was made under difficulties and the politzer applied, and the cleansing and dressing as in the previous case followed out. For three days I saw this child twice a day and renewed the dressings. I used the politzer each time and carefully cleansed the ear with cotton probes, until the temperature dropped to 99° and the child was feeling better, and appeared to be in excellent spirits. The parents who now wished to undertake the treatment were given this privilege, under protest, with the result that on the third day thereafter I had to reopen the drum, due to a premature closure, and a sudden rise of temperature to 105.2°. It took four days to bring the temperature down to normal, but there were still evening exacerbations to 100°. A second consultation was asked for with one of my colleagues, who advised operative interference, viz., opening the mastoid. I personally could not persuade myself to believe that there were any urgent indications for any such procedure. The small rise in temperature, in my mind, was simply due to a toxemia, due to the poor powers of resistance on the part of this little patient. I was very much averse to producing a still further tax upon this child, first, in the way of an operation, and, secondly, exposing a large, raw surface for the further absorption of toxic material. I was finally allowed to proceed with my plan of treatment, Dr. Koplik carefully looking after the constitutional condition of the child. This patient was dressed daily by myself for three consecutive weeks, and recovered completely in a period of eight weeks. The only additional treatment used besides the dressings and the politzer was aspiration with the Delsanche. I have found frequently that after the unsuccessful use of the politzer, the Delsanche will still succeed in bringing some secretion into the canal.

Case IV.—The brother of a physician had been suffering for some time from a catarrhal otitis media and developed suddenly an acute otitis media purulenta. I saw the patient in the second week of his attack, when he had already developed mastoid symptoms. The patient was not a robust individual. On examination he presented the following conditions: A chronic otitis media purulenta of about ten years' duration, with periods of quiescence, was present in the left ear. The tympanic membrane here showed a perforation high up posteriorly, just below the posterior fold and on the margin. The membrane was retracted and of a dirty grayish color. There was no tenderness on pressure over the mastoid, but some over the antrum. The discharge had a slight odor. The right ear was in an active state of inflammation. The tympanic membrane was bulging throughout its entire extent and reddened.

Between the posterior superior portion of the canal and the tympanic membrane no sharp, distinctive line could be discerned. At first no perforation could be seen, but with the help of a Siegel's speculum this was quickly found, posteriorly, just behind the short process of the hammer, and below the posterior fold. There was tenderness on pressure over the mastoid and over the antrum. The latter was exceedingly sensitive. The temperature taken by mouth in my office was 100°. The left ear was unimportant so far as urgent treatment was concerned, but there was no time for delay in regard to the right ear. A paracentesis was made, followed by politzeration and the use of Delsanche, with thorough cleansing, drainage, and the application of a wet, occlusive dressing. The patient was sent home and told to keep quiet for the rest of the day. The left ear was cleansed and the usual measures advised which are employed for these chronic conditions. After two weeks of daily dressings and cleansing the patient had improved to such an extent that I thought it wise on account of his poor general condition to send him off into the country. This had a most beneficial effect, not only on the right ear, but also on the left ear. After ten days he returned with his right ear well and his left ear very much improved. After two weeks more the left ear had again become quiescent, so that when I discharged the patient he was practically well.

Case V.—The patient, M. N., was referred to me by Dr. B. Sachs. For two months he had been suffering with pain and profuse discharge from his right ear. About the middle of September, the pain had become severe and extended over the right side of the head. At the time of the examination, which took place on September 29, it was impossible for him to extend, flex, or rotate the head without excruciating pain. Even the attempt to open his mouth gave him severe pain over the temporomaxillary articulation. There was no tenderness to pressure over the lower portion of the mastoid, but as one approached the region of the antrum and the root of the zygomatic process, there was distinct tenderness. The canal was filled with a bad smelling secretion, which, after being wiped away, revealed a tympanic membrane that was bulging very markedly over the anterior and posterior superior portions. Close to the short process of the hammer and above it was a nipple-shaped perforation. There was no edema over the mastoid or within the canal. The temperature taken at my office was 101.2°; the pulse ranged between 84 and 100, and was irregular. The patient was a poorly nourished, anemic looking individual, and very much depressed; the latter condition due to the fact that he had been told that he was a very sick man, and that only an immediate operation might save his life.

An examination of the optic discs and bloodvessels proved negative. The pain produced by the movements of the head were purely muscular. It was aggravated only by muscular contraction, not at all by pressure upon the muscle. There was an absence of the painful pressure points, so characteristic of neuralgia, and not the slightest paralysis or contracture so conspicuous in neuritis. There was simply a stiffness of the head. The pain over the temporomaxillary articulation is not at all uncommon in a great many cases, when there is a large cell in the root of the zygomatic process which communicates freely with the antrum. In these cases when an empyema exists within the antrum, it is apt to spread very rapidly towards the root of the zygomatic process. The diagnosis arrived at in this case was an otitis media purulenta, complicated by an empyema of the antrum.

In regard to the treatment, my plan of procedure was as follows: As all the symptoms pointed to a lack of proper drainage, I was willing to allow this patient forty-eight hours more to respond to the following measures. The usual incision, politzer, aspiration, cleansing, drain and dressing as in the above cases was carried out. Salol, 5 grains, every three hours was given for his rheumatic pains. He was sent home with instructions to keep absolutely quiet, and, if there was no temperature, to return

to my office on the next day. On the following day his condition had very much improved, and within thirty-six hours from the time of the paracentesis, an operation was no longer considered necessary. After the third day the patient was advised to spend the greater part of the day out of doors, salol to be taken three times daily, good, nourishing food, with the addition of a tonic of iron, was prescribed, and after two weeks the ear had ceased to discharge.

Case VI.—A child of two years of age was referred to me by Dr. Waller. This little patient, after an attack of bronchopneumonia at the age of eleven months, suffered from a recurrent acute otitis media purulenta, which perforated the drum of its own accord each time, and after the third attack refused to get well. After four weeks of constant discharge, and the sudden appearance of temperature and pain over the mastoid region, the child at the same time becoming very fretful and looking poorly, I was asked to see him. The temperature taken at my office was 100.4°. On the right side, over the mastoid and antral regions there was distinct tenderness to pressure. The drum was swollen, reddened and bulging very markedly, probably a little more over the posterior superior quadrant than in the other portions. On the left side the drum was also reddened and bulging, but there was no tenderness to pressure over the mastoid or antral regions.

In regard to the diagnosis in this case, on the right side we undoubtedly had to deal with an acute otitis media purulenta and empyema of the antrum, together with a stagnation of the secretion due to the small perforation. On the left side, there was a beginning acute otitis media. Although I understand that this child had had its hypertrophied pharyngeal tonsils removed twice, the nasopharynx again revealed a soft mass still present in this region. The child was sent home, and that same afternoon, under anesthesia, the adenoids were removed, a paracentesis was done on both drums, and the usual treatment as above described was carried out with especial care on the right side. The temperature rose to 101.5° that same evening, but on the following morning dropped to normal. There was a slight evening rise to 99.8° for three consecutive days. The tenderness to pressure began to diminish after the third day, and at the end of ten days disappeared entirely. After three weeks the right ear ceased to discharge. The left ear recovered ten days after the removal of the adenoids.

Thus I might go on relating the histories of other individual cases, but I deem the above number sufficient for my purpose. I have seen an adequate number in my private practice and in my clinic at St. Luke's Hospital to convince me that more conservatism is allowable in these cases than we suspect.

In regard to the treatment, I wish to emphasize one fact in particular, viz., that I have not allowed myself to be influenced by either the etiology or the bacteriological findings, so far as operative procedures are concerned.

The presence of streptococcus undoubtedly means a severe infection. It does not mean, however, an immediate operation. Such patients will have their strength taxed to their very utmost. In these cases the most rigid cleansing, drainage, and constitutional support will be demanded of us. Simply because a patient has been suffering from an acute otitis media purulenta for two weeks, and suddenly develops a temperature of 104°, with mastoid symptoms and the presence of the above bacteriological findings, would not persuade me to adopt at once radical measures. I should certainly, first of all, employ the conservative treatment, and if within thirty-six hours there was no *decided improvement*, then there should no longer be any hesitation. If the improvement is only temporary, and there is no ascertainable reason for a second exacerbation, then, again, operation should be advised. In simple and acute cases, with mastoid complications, I prefer to wait from four to six days before advising operative interference, at all times bearing in mind that urgent symptoms would at once call for a radical operation.

Considering for a moment the plan of the above treatment in detail, it will be noticed that the primary object of everything that is done is for the purpose of accomplishing a thorough drainage.

First of all, in regard to the incision. This is made with a sickle-shaped knife, which allows a liberal incision to be executed rapidly. I prefer it to the straight knife and the lance needle, which I would not use under any circumstances. This incision must extend through the posterior superior portion of the canal and throughout the entire posterior portion of the drum. I at once follow this with the politzer and blow out all pent-up secretion in the tube and tympanic cavity. Remember that this ear is in a state of acute inflammation, that the mucous membrane of the Eustachian tube, middle ear, antrum, and undoubtedly that of the greater part of the mastoid cells are, more or less, in a state of tumefaction, and that the point of least resistance is the opening in the drum. That a current of air directed through the nose, Eustachian tube, and middle ear would certainly take this direction of least resistance, and pass into the external auditory meatus. That this does so, together with varying quantities of fluid secretion, is without doubt. You have only to employ this measure once to convince yourselves. To blow secretion from the throat of such a patient into his middle ear, through a tube which is already partially closed on account of the swollen mucous membrane, unless undue force is used, is a statement which I most severely question. To blow it into the mastoid cells, when there is a large opening in the drum, and at the same time remembering that these cells are probably shut off from communication by a swollen mucous membrane, I am unwilling to believe.

I dwell upon these last two statements because you will be warned on all sides against using a politzer in acute affections of this kind, as you are liable to infect the middle ear with secretion from the throat, or blow the secretion into the mastoid cells. If the politzer is unsatisfactory in this respect, I make use either of a Siegle's speculum or the Delsanche instrument to aspirate the secretion. Remember, I am referring to protracted cases, where you would always expect to find secretion. It takes from twenty-four to thirty-six hours in primary acute cases for the secretion to form. The secretion is now most carefully wiped out with absorbent cotton wound on probes until the ear is as clean as it is possible to make it. As a drain, and at the same time to exert a beneficial influence upon the edema within the middle ear and surrounding parts, I place a piece of strip iodoform gauze wet in a 10 per cent. solution of Liquo Burowii, and over the entire ear and surrounding parts, an occlusive wet dressing of the same solution. This treatment is continued daily until the acute symptoms have passed off, when the wet dressings are left aside, and simple cleansing measures are carried out. It is very often necessary to probe the opening in order to keep it from closing too early.

Now, I do not wish to claim that this treatment is so ideal that every case will respond to it. I am still very far from any such idea, but what I do wish

to emphasize, is that we should hesitate advising radical operative procedures, before we have convinced ourselves that the symptoms present are urgent enough to warrant such interference. If the opportunity is given to a competent man to watch and handle such cases daily, it is hardly possible that he will overstep the danger line of conservatism. In a great many cases the cause of our failure with the conservative method lies in the fact that we pay too much attention to the local treatment, and very little, if any at all, to the constitutional treatment. If we would only stop and think a moment, it would be seen that most of these protracted and severe cases come on in patients after infectious and exhausting diseases. These have already taxed the patients to their utmost, and placed them in our hands when there was very little recuperative power left. A great deal can be done, however, for such patients, by means of good hygienic treatment—fresh air and sunshine, and plenty of it; good, wholesome food, and a proper regulation of baths. In the way of tonic treatment, iron and cod-liver oil are of especial value. In rheumatic cases, salol will prove very beneficial.

In our eagerness to prevent our patients from approaching the danger line, we have slighted our conservative principles, and are in danger of becoming too radical. Otology has advanced to such a degree, that to-day the principle, "operate one case too many rather than one case too few," is no longer tenable. When the privilege is accorded you to observe carefully your cases, you will certainly uphold your good surgical reputation just as much through conservatism as through radical measures.

A MODIFICATION OF THE HELLER TEST FOR ALBUMIN IN THE URINE.

By ABBOTT SMITH PAYN, M.D.,
NEW YORK

The object of the Heller test is to precipitate albumin in a suspected urine by the contact of the urine and nitric acid. As is well known, the test is performed by placing a small quantity of clear, colorless nitric acid in a test tube and overlaying the acid with the urine. This is accomplished by inclining the tube and allowing the urine, from a pipette, to run slowly down onto the acid. At the line of contact, if albumin be present, there may appear a white line or zone.

There are times, especially in the event of very small quantities of albumin, when this cold contact test gives a negative result, although a positive reaction may be obtained in the same urine with the potassium-ferrocyanide test. This discrepancy in the cold Heller is overcome by the use of the modification to be described presently.

It is important that the urine be perfectly clear before attempting the Heller, less so the modification. Filtration may clarify the urine if the turbidity be due to mixed urates, crystals of urea nitrate, or earthy phosphates, and to a less degree or not at all if the turbidity results from the presence of mucus, pus, fat, or bacteria. Heat in most instances will dissipate the urates and phosphates if amorphous. The other ingredients are either not affected by it or heat increases the turbidity. Resins are dissolved by the addition of a few drops of alcohol. Resins, notably copaiba, when ingested cause the formation of a zone at the contact in the Heller test; this is a dirty yellow. A drop or so of alcohol to the urine will dissolve the resin. It is of interest to note that if albumin be present the alcohol will aid in its precipitation. The zone of albumin is always white. A violet line at the contact is due to decomposed indican. A reddish zone indicates an excess of uric acid, and an olive zone an excess of bile. Above the contact—in the urine—a haziness may be noted. This is due to mixed urates, phosphates, crystals of urea nitrate, mucus, or bacteria.

It is at this point that the modification of the Heller test is of twofold advantage. It may be performed thus: Place the inclined tube—which contains the Heller as described above—in a low flame and heat the urine; urine only, not the acid, just short of ebullition, that is to a single bubble, care being taken not to disturb the contact. Set aside for a few moments. Examine by placing the tube against a dark background, and it will be noted that the urine is not only clarified, especially if the turbidity was due to the urates or phosphates, which is usually the case, but at the line of contact there will be found precipitated small quantities of albumin not apparent when the test is performed cold.

545 West One Hundred and Forth-eighth Street.

Pneumonia from the Practitioner's Standpoint.—Wm. E. Anderson believes that the percentage of deaths from pneumonia is much larger than it should be. The strongest point in the treatment of this disease, he declares, may be termed individualization. He generally uses strychnine, and has never had any occasion to regret it. It has a good effect on both the heart and nervous system. He also uses in nearly every case quinine, from 5 to 60 grains a day. When the pulse indicates its use, digitalis should be given. The heart should be fortified from the beginning, and peripheral circulation should be encouraged. In cases of much consolidation and slow resolution, a cantharidal plaster is of great use. The patient should be well sustained by good concentrated liquid nourishment, and in the later stages alcohol, whiskey or brandy, when needed, should be given. The writer believes that alcohol is first a stimulant, and afterwards a sedative. When the respiration gets much above 40, it is well to use oxygen inhalation. Plenty of pure water should be given, as this is most important. As much salt in the food as can be relished is very useful. In nearly all cases of pneumonia the deficiency of chlorides in the urine may be noted. The writer has treated several hundred cases of pneumonia, and has lost only two cases. One of these patients developed a large abscess of the lung, and in the other tuberculosis followed rapidly upon pneumonia, or probably existed prior thereto. The writer urges the careful study of the conditions of each case, and the application of common-sense principles. He believes if more attention were given to the patient and less to the theory of the disease, the death rate would be greatly diminished.—*Virginia Medical Semi-Monthly.*

The Sterility of the Skin.—Klemm, in attempting to analyze the factors concerned in the production of the inexplicable stitch abscesses and other infections which from time to time occur in clean wounds, comes to the conclusion that air infection hardly requires consideration in this connection. The risk of contact infection also, produced through the hands of the surgeon or his assistants, may be reduced to an unimportant degree through careful methods of hand disinfection. It is the skin of the patient that is the weak point of modern surgery, as we have no means at our disposal for rendering the operative field entirely germ free. Germs transported into the wound from the surgeon's hand or from other sources must first adapt themselves to the new environment, and many of them perish in the attempt; but the autocthonous organisms deep in the lower layers of the skin are only awaiting an opportunity to develop under familiar conditions. Of forty sutures extracted from wounds under aseptic precautions, that had run an aseptic course, not a single one was found sterile, showing that whether infection appears or not is largely a matter of individual powers of resistance of the tissues. The author believes that we have gone as far in this direction as is possible, and that even after all precautions have been taken there will always be some chance of a wound doing badly.—*Deutsche Zeitschrift für Chirugie.*

MEDICAL RECORD.

THE INFLUENCE OF HABITATION ON TUBERCULOSIS.

DR. SAMUEL BERNHEIM, writing in the *Revue Internationale de la Tuberculose* for November last, subjects the importance of the house factor in the spread of tuberculosis to a searching examination. He concludes with Brouardel, that "the house is the foe; the unsanitary lodging." The article is unfortunately too long for us to give more than a brief outline, but it is one which will repay reading in full. Bernheim marshals a series of the most reliable statistics to prove his conclusion. The studies of Lancereaux on the geographical distribution of tuberculosis show that it is unknown among savages. It is, in fact, a disease of civilization, or as Hauser of Madrid says, it is a social disease, and one that society alone can eradicate, by subjecting its members to the laws of individual hygienic life. The movement city-ward, so characteristic of modern civilization, has created veritable foci of tuberculosis. Thus while of 300 immigrants from the provinces into Paris who developed tuberculosis, only 15 (or 5 per cent.) were sick previous to their arrival in the city, Launois and Bourgeois show from a quarter century's records at the Hôpital Tenon, that tuberculosis constitutes 46.7 per cent. of all cases on the medical side, and that two-thirds of the cases occur in immigrants. Again the prevalence of the disease in cities may be inferred from Letulle's record of 189 autopsies for non-tuberculous affections, which yielded: Exempt from all tuberculous lesions, 79; latent or cured tuberculosis of the respiratory passages, 92; suspected cases, 18. Also the statistics cited by the author prove that the disease is more prevalent in the larger than in the smaller cities. What factors determine the distribution of the disease within the cities themselves? Of these all that group of influences which go to make up pauperdom are the most important. For example, the amount of annual income exerts a marked influence. Thus in Hamburg, the deaths (referred to 10,000 of the population) are: For annual incomes over 3,500 Marks, 10.7; 3,500 to 2,000 M., 20.1; 2,000-1,200 M., 26.4; less than 1,200 M., 29.3; less than 900 M. (estimated), 60. But of all the influences comprised in this group, overcrowding plays certainly the chief rôle. Thus in Budapest, the mortality figures run: With 1 to 2 persons in a room, 20; 3 to 5 persons, 29; 6 to 10, 32; and above 10, 79. The better districts in Marseilles show a rate of 20 per 1,000, as against 46 for the worse. In Vienna in the districts where 9 per cent. of the lodgings are crowded, the rate is 25 per 1,000, whereas in those in which only 1 to 2 per cent. are crowded, it is only 17.22 per cent. In the Duchy of Baden, Kugler found in 1890, that where 1,000 persons inhabited 845 rooms, the mortality was 2.29; while with 745 rooms it was 2.66; with 645 rooms, 3.10; and with 547 rooms, 2.30. For the city of Baden, given 800 rooms per 1,000 persons, the mortality was 2.20; with 500 rooms, 3.03.

Moreover, in these pest spots cases of tuberculosis do not occur isolated, and one can be sure that in an undisinfected room or house where a tuberculous patient has lived or died other cases will develop. Thus Biggs and Meyer have shown that in the poorer districts of New York cases follow on one another rapidly. In certain houses with 28 to 36 persons, as many as 9 to 12 cases have occurred in three years. And in one district, 10.5 per cent. of the houses have yielded 55.8 per cent. of all the cases of tuberculosis. In Bernheim's own investigations into the histories of 340 cases in previously powerful and robust persons (all alcoholics and hereditarily predisposed persons being excluded and only cases being taken in which no other cause than direct acquisition could be supposed), the lodging was incriminated 124 times; that is, it was known to have formerly harbored tuberculous subjects. One anterior contagion was demonstrated 99 times; two, 14 times; and three, 11 times. Also a number of instructive instances are cited, which are with difficulty explicable on any other assumption than that the lodging was responsible. For example, every one of a family of eleven persons coming from the provinces contracted tuberculosis after living in a lodging in which a tuberculous patient had died. The lodging had not been disinfected.

The danger may last several months or several years. Koch found dried tuberculous matter still virulent after six to eight weeks. Also Galtier had a similar result with such matter dried and exposed to temperatures below 30° F. And Cadiac and Malet found the bacilli to retain their virulence even after 100 days. On the other hand Straus has destroyed them by half an hour's exposure to June sunlight.

The author then analyzes the other factors which go to make up the sanitariness or unsanitariness of the lodging; the amount of floor space, of cubic space, the number of windows, etc., and shows that each of these is faithfully reflected in the cold, unsympathetic figures. Like the mills of the gods, though slowly, they grind exceeding small. Into all these details, however, we cannot follow him.

The measures found necessary, in the light of this study, are then discussed. What can be effected in the way of remedying the condition of the habitation is shown by the general reduction in England of the mortality from 23 to 18 in consequence of the adoption of a hygienic sanitary code and the enforcing of severe sanitary police regulations. In Edinburgh the mortality of 25.8 dropped to 18.8 after the prosecution of important works of sanitation. The only remedy for these conditions then lies in a thorough sanitary surveillance by competent medical authority, of all lodgings, with plenary powers to require the necessary remodeling (and if that will not suffice the demolition) of the premises. Tuberculosis should be classed among the diseases

whose report to the sanitary authorities is obligatory, and the disinfection of all lodgings occupied by such cases should be done by those authorities. Tuberculosis being a contagious disease, every patient affected with it should have a bed to himself, and where in family life this is not possible, he should be sent to a hospital. The reports on the sanitariness of lodgings should be open to the public. These measures in their entirety constitute, Bernheim holds, the best means for the suppression of the disease.

FIRST AID IN NAVAL WARFARE.

In the *Journal of the Association of Military Surgeons* for March, Dr. John Cropper Wise writes, or rather reviews recent literature, on this subject. Three articles dealing with the matter have been recently written by officers of the English, French, and Spanish services respectively. The important questions at issue, according to Dr. Wise, are: (1) The location of dressing stations; (2) the station and duties of medical officers during an engagement; (3) emergency dressing.

Dr. Juán Redondo of the Spanish navy says that in regard to dressing stations, the planning of places suitable for the wounded has been unjustifiably disregarded. The essential conditions of a dressing station he states as follows: (1) It should be such a point as might be called strategic, that the wounded may be brought to it without much difficulty; (2) it should be protected from the enemy's fire; (3) it should have direct communication of its own with the deck and batteries. He recommends two dressing stations, one forward and the other aft, and considers that these stations are the proper post for the medical officers during battle.

Referring to the first aid package, Dr. Redondo is of the opinion that it is unquestionably of great use in land battles, but has comparatively little value in warfare at sea, owing to the severe nature of the injuries which the men do not possess the knowledge to dress.

Dr. De Forges of the French naval service says that there are no *postes de blessés,* properly speaking (on the *Pascal,* his ship), because of lack of space under the protective deck and also on account of the great difficulty of access. "What then will become of the wounded during the combat? They will be laid aside by their comrades, in such manner as not to interfere with the fire of the guns or of those serving them." As to the station of the medical officers, the same writer holds the view that the surgeon should remain under protection during fire and should do nothing until after the action. He also states with emphasis that relief should be attended to solely by the medical officers.

Dr. Randall of the British naval service expresses opinions in direct opposition to those of the French and Spanish medical officers. He says that in the fighting line only first aid should be rendered the wounded, and for this purpose dressing stations should be established where possible and convenient. The medical officer and his assistants, he says, should be free to move about the ship, as expeditiously as they can, and wherever they are most urgently needed, as for instance, in a casemate wrecked by a shell.

Dr. Wise is distinctively of the opinion that the French and Spanish views that the medical officers should remain under protection during an action and not attempt to attend to the wounded until after the fight is over are unwise in many ways. Not to treat the wounded during a sea combat would be to deny the very object of a medical department's existence, and, furthermore, the effect on the morale of the fighters would be bad.

Toxicosis Resulting from the Modern Cold Storage Methods.

A paper on the above subject was read by Dr. M. Cavana at the fourteenth annual meeting of the New York and New England Association of Railway Surgeons, held in New York City, November 17 and 18, 1904. Poisoning by means of food is frequent nowadays, owing to the manner in which adulteration is carried on, and to the methods used in preserving food products. Dr. Cavana pointed out that in spite of the increasing number of cases of sudden and violent attacks of illness resulting from food poisons, little or nothing has been done either by our legislatures or by the medical profession to protect the people. The most frequently recognized of the toxinfections is that form due to food infection and is generally the result of eating such flesh food products as have become partially decomposed from long periods of storing in the modern cold storage plants. The author showed that 80 per cent. of the cases of exogenous toxicosis in New York State resulted from poultry foods alone, in his opinion due principally to the filthy and abominable practice of cold storage companies of storing poultry for months, and even years, in its undrawn or undressed state. Attention is drawn to the reports of the New York State Board of Health which show that eight thousand deaths occur from diarrhea in a single year. The large majority of these fatal cases, Dr. Cavana asserts, are due to food toxicosis. Finally, the writer declares that the time is ripe for radical action in this important field, and the medical profession should exert itself to secure legislation which would go far towards putting an end to this form of exogenous toxicosis.

Investigations Into the Plague.

In the *Journal* of the Royal Army Medical Corps for February, 1905, Dr. T. P. Smith, reviewing some current medical literature, refers to a few remarks on the resistance of the plague bacillus, its presence in the blood of patients, and the part played by fleas, which were published by M. Uriarte, director of the Epidemiological Laboratory at Buenos Ayres, in *Le Caducée* of October 1, 1904. M. Uriarte had left untouched seventeen cultures of the plague bacillus, made in October, November, and December, 1899, the object being to estimate the duration of the vitality and virulence of the microbe. These cultures were used on February 28, 1904, and gave fourteen positive results. The most interesting of the investigations were those in which attempts were made to discover whether fleas of the rat could bite human beings. Of the insects found on rodents caught near a plague focus, eighty-two belonged to the species *Pulex irritans,* and four to *P. serraticeps.* Men were bitten by some of both kinds, even when the insects were not fasting. The determination of the species showed that fleas found on rats do not always belong to the species that usually occur on these rodents. Further experiments, like those previously published, show that fleas of the species *P. irritans,* caught on rats

suffering from plague, by simply passing over the surface of jelly, cause the appearance of many colonies of the specific microbes, which are also to be found in the intestines of the insects.

The Defense Against Diphtheria.

In the weekly bulletin of the Chicago Health Department for March 25, the statement is made that "no child dies of diphtheria to whom 3,000 units of antitoxin are administered within the first forty-eight hours of the attack—repeated, of course, if necessary." Ten years ago the antitoxin treatment of diphtheria was begun by the Department. During the previous ten years ended December 31, 1894, there had been 13,566 deaths from diphtheria and croup reported to the Bureau of Vital Statistics, a yearly average of 1,356, and a proportion of 13.53 deaths in every ten thousand of the population. During the ten years ended December 31, 1904, there were only 8,129 such deaths reported, a yearly average of 812 and a proportion of less than 5 (4.88) in every ten thousand of the population. These figures show a reduction of 5,437 in the actual number of diphtheria and croup deaths since the Department began the antitoxin treatment. They show a relative reduction, in proportion to increased population, of nearly 64 per cent.—63.9. Which is to say that, if the ravages of diphtheria had not been checked by the use of antitoxin during the last decennium, there would have been 22,538 deaths from this former scourge of the nursery, instead of the 8,129 that did actually occur—a probable saving of 14,409 lives.

News of the Week.

Cerebrospinal Meningitis.—There were 131 deaths from cerebrospinal meningitis reported in this city during the week ending April 1, an increase of 46 over the total for the previous week. In Cleveland 35 deaths have occurred from this cause, and the health authorities are beginning to be seriously alarmed at the prospect of an epidemic. The total number of deaths from the disease in Boston is so far 25 as against 14 for the corresponding period last year, and 37 for the entire year of 1904. Middletown, N. Y., and Lowell, Mass., are also showing numerous cases. A despatch to *The Sun,* dated April 2, states that an epidemic of cerebrospinal meningitis is causing many deaths in Silesia. In the Kattowitz district 450 cases have been reported, 37 per cent. of which have proved fatal. A number of cases are reported at Konitz and Czersk, and the residents of these towns are becoming alarmed. Many have already left Czersk. The government has now forbidden migration from the infected districts. Some cases have also occurred in Berlin.

Typhoid Fever in Philadelphia.—During the month of March 1,054 cases of typhoid fever, with 91 deaths, were reported to the health authorities in Philadelphia. In February there were 600 cases. The last week of March showed a falling off of seventy-five cases, the total being 231 new cases as compared with 306 returned the week before. There was an increase of more than 100 per cent. of deaths from the fever, however, thirty-two dying, as compared with fifteen for the week before. The fever is worst in the northeast section of the city, which is getting filtered water, and is less prevalent in the wards receiving unfiltered Schuylkill.

Low Death Rate at Panama.—According to a communication received by the War Department from Governor Davis, sanitary conditions in the canal zone are steadily improving. During the month of February the number of sick in hospital was less than 2 per cent., and the death rate was less than one-fifth of that suffered by the French in 1881. The last case of yellow fever to occur in Panama was on March 8, and the last case in Colon on March 18. The total number of cases among the entire population on the isthmus during January was 101; during February there were 13, and during March, 9. The present sanitary force consists of over 1,000 employees, costing over $25,000 monthly.

Investigating an Epidemic in Hawaii.—The inter-island steamship *Likelike,* chartered by the territorial government, has left Honolulu for Pelekunu valley, on Moloki, carrying Army Surgeon Yost, eight men of the hospital corps, and two nurses. It is a relief expedition, sent out on account of reports of an epidemic in the form of an unknown sickness believed to be typhoid fever. Eight deaths have already taken place. There is no doctor on the island, outside of the practically inaccessible leper settlement.

Complaint of Neglect of Duty by Health Boards.—The State Board of Health has made complaint that the local boards are very lax in the matter of filing birth certificates and the registration of marriages. Section 22 of the public health law makes it mandatory on the part of all local boards of health to supervise and make complete the registration of all births, marriages, and deaths occurring in the municipality, and to forward the certificates promptly to the Bureau of Vital Statistics. The registration of deaths is considered nearly complete, but the others certainly are not.

Health Department Census.—One hundred and fifty inspectors have been appointed to take a new census of the city for use of the Health Department. The inspectors will receive $100 a month. The census will cost approximately $35,000, which has already been appropriated. While the census will be complete for the city, it will cover health and sanitary conditions especially, and the congested tenement districts of the city will receive the most careful attention.

Medical Association of the Greater City of New York.—At the meeting of this society on April 10, there will be a symposium on immunity and serum therapy, papers being read by Drs. H. K. Dunham of the Carnegie Institute, Eugene L. Opie of the Rockefeller Institute, H. T. Marshall of the Johns Hopkins Hospital, H. D. Pease of the New York State Board of Health, and H. W. Berg, of the Willard Parker Hospital, New York.

Parasitic Larvæ in the Human Tissues.—Mr. F. L. Washburn of St. Anthony Park, Minn., State entomologist, writes that as the fact that the larvæ of dipterous insects, "maggots" or "bots," are sometimes found in human subjects is one of interest, not only to physicians, but to entomologists, he would be grateful, should any such case come to any physician's attention, if the latter would send him specimens of the maggots *alive,* in moist cotton or in earth, that they may be reared and their identity established beyond a doubt. In return, Dr. Washburn will be glad to give any information which the possession of the parasites in the Experiment Station laboratory may produce. It is sometimes very difficult, and even impossible to determine the genus and species accurately from structural characters of larvæ of flies, hence the necessity of procuring the same alive and rearing them to the adult stage.

The Fiftieth Anniversary of a Manufacturing Drug House.—The house of Frederick Stearns & Co. of Detroit was established fifty years ago by Mr. Frederick Stearns, who removed to that city from Buffalo in 1855. He opened a drug store there and con-

structed a laboratory in a small back room. In this laboratory, equipped with a cook-stove, he began the manufacture of a few pharmaceutical preparations, and gradually established a trade in the State. In 1882 the business was incorporated, and in 1887 Mr. Frederick Stearns, after a business life of over forty years, retired and was succeeded in the presidency of the company by his son, Mr. Frederick K. Stearns. The current issue of *New Idea* contains a history of the house and portraits of the founder and of the leading men of the company.

A Farewell Dinner to Dr. William Osler will be given at the Waldorf-Astoria in this city on the evening of May 2. Information regarding the same may be obtained by applying to Dr. James Tyson, chairman of the committee, 1506 Spruce Street, Philadelphia.

Healers' Bill Vetoed.—The Legislature of Nebraska passed a bill requiring all "healers" to take a four years' course in medicine and to pass the examinations required of regular physicians. The bill originally included Osteopaths and Christian Scientists, but a strong lobby forced the physicians to agree to amendments which exempted Osteopaths. The governor vetoed the bill on the ground that it was unconstitutional.

To Check the Spread of Consumption.—An ordinance passed by the Municipal Assembly of St. Louis provides measures to prevent the spread of consumption. Physicians hereafter will be required to notify the Health Commissioner of cases of consumption just as they are required to report all contagious diseases. Houses, however, will not be placarded, but the Health Department will supervise the control of consumptive patients, and in extreme cases have the power to isolate them.

Gift for a Day Nursery.—The Jewish Charitable and Educational Society of St. Louis will erect a building to be used for a day nursery and kindergarten for the poor children at a cost of $10,000, which sum has been donated by Mr. and Mrs. Elias Michael of St. Louis.

"Gaillard's Southern Medicine" is the name which has been adopted for the journal formed by the amalgamation of *Southern Medicine* and *Gaillard's Medical Journal.* Dr. William Edwards Fitch continues in editorial charge of the journal.

Resolution on Commissions.—At a recent meeting of the Chicago Medical Society, the following resolution was submitted to and adopted by the Council of that body: "It is derogatory to professional character for physicians to pay or offer to pay commissions to any person whatsoever who may recommend to them patients requiring general or special treatment or surgical operations. It is equally derogatory to professional character for physicians to solicit or to receive such commissions."

Contract Work Harmful.—At a meeting of the Northwest Branch of the Chicago Medical Society, recently held, the following resolutions were adopted: (1) That it be the sense of the Northwest Branch of the Chicago Medical Society that contract work is harmful to the best interests of our Society, and should be abolished; (2) that the minimum fee should be as follows: Visits, $1.50; office visits, $1.00; normal obstetrical case, $15.00; (3) that this Branch heartily endorses the establishment of a business bureau by the Chicago Medical Society.

Tennessee State Medical Association.—The seventy-second annual meeting of this association will be held at Nashville on April 11, 12, and 13, under the presidency of Dr. Paul F. Eve. The programme contains thirty-two titles of papers announced for this meeting, and in addition there will be a public discussion on the "Prophylaxis of Tuberculosi" on the evening of April 12. The secretary of the association is Dr. Deering J. Roberts of Nashville.

Defective Hygiene in the Spanish Army.—At the recent meeting of the Spanish Academy of Jurisprudence in Madrid, Dr. Canalejas, in his presidential address complained bitterly of the wretchedly defective army hygiene. He said that in Spain the mortality in the army was 11 per cent., while in France it was only 5 per cent. It was the inadequate sanitary arrangements, which Señor Canalejas himself saw in the Cuban hospitals, that were responsible for the terrible mortality in the Spanish-American War.

Herkimer County Medical Society.—At a meeting of this society Dr. W. B. De Garmo of New York read a paper on hernia, and the following officers were elected: *President,* Dr. Williams of Newport; *Vice-Presidents,* Dr. A. C. Douglas of Ilion and Drs. Ellis and Brainard of Little Falls; *Secretary,* Dr. Suiter of Herkimer; *Treasurer,* Dr. Graves of Herkimer.

Appropriation for City Hospitals.—The Board of Estimate has sanctioned an issue of $1,000,000 of bonds to be used by the Board of Health in improving the city hospitals. The board also voted $750,000 to improve the sanitary condition of Gowanus Canal, which has long been regarded as a menace to health. It will be deepened and new inlets provided so that fresh water will enter the canal twice daily.

Dr. Lucy A. Bannister who for four years has been superintendent of the Mills Training School for Male Nurses, at Bellevue Hospital, has resigned from this position in order to go into the practice of medicine in Philadelphia.

Clark County Medical Association.—At the recent meeting of this association, held at Kahoka, Ia., the following officers were elected: *President,* Dr. Dickson; *Vice-President,* Dr. Sisson; *Censor,* Dr. Shanks; *Secretary* and *Treasurer,* Dr. A. C. Bridges; *Counsellor,* Dr. F. B. Hiller.

University of Minnesota.—A new medical building is to be added to the equipment of the university at a cost of $100,000. Aside from the university medical department, the new building is to be a home for the state board of health, and a Pasteur institute.

The Society of Sanitary and Moral Prophylaxis will hold a meeting at the Academy of Medicine, on Friday evening, April 14. The society will adopt a constitution and by-laws, and papers on sexual hygiene and allied subjects will be read by Drs. John H. Elliott, Edward L. Keyes, and Prince A. Morrow, the Rev. Henry A. Brann, and Mr. Frank Moss. The papers will be discussed by members of the laity and of the medical profession.

Dr. Lewellys Franklin Barker, now head of the Department of Anatomy in the University of Chicago and Rush Medical College, was elected by the trustees of Johns Hopkins University, at a meeting held April 3, to the Professorship of Medicine, made vacant by the resignation of Dr. William Osler. At the same time Dr. William Sydney Thayer, Associate Professor of Medicine in Johns Hopkins, was elected Professor of Clinical Medicine.

Crawford County Medical Society.—The following officers were elected at the last meeting of this society: *President,* Dr. E. D. Helfrick of Galion; *Vice-President,* Dr. C. A. Marquart of Crestline; *Secretary,* Dr. Lewis Yeomans of Busyrus; *Treasurer,* Dr. Catherine Rayle of Galion; *Member of the Board of Censors,* Dr. J. F. Fitzsimmons of Busyrus.

Obituary Notes.—Dr. William Bodenhamer died at his home in New Rochelle, N. Y., on March 31, at the age of ninety-seven years. He was born in East Berlin, Pa., and was graduated in medicine from the now defunct Worthington Medical College, the medical department of Ohio University. He practised successfully in Paris and Louisville, Ky., and New Orleans, and come to New York in 1859. During his active medical life he was an authority on diseases of the rectum, and even after his retirement continued his studies in this department of surgery, and occasionally wrote on the subject for the medical journals.

Dr. Frank H. Rice died at his home in Passaic, N. J., on March 27, at the age of seventy-five years. He was a graduate of the Medical Department of the University of Vermont, in the class of 1855.

Dr. Richard H. Sullivan died at his home in Brooklyn, on March 27. He was born in Brooklyn and was graduated from the New York University Medical School in the class of 1883.

Dr. Willis P. Spring died at Minneapolis on March 23, at the age of fifty-one years. He was a graduate of the Harvard Medical School in 1879. He was formerly coroner of Hennepin County, Minn. He was an enthusiastic student and worker in electrotherapeutics and radiology.

Dr. John W. Gamwell of Pittsfield, Mass., died suddenly at Daytona, Fla., on March 26. He was born in Washington, Mass., in 1830, and was graduated from the Berkshire Medical College in 1852.

Dr. George F. Corse, died at his home in Baltimore on March 23, at the age of sixty-five years. He was a graduate of the University of Maryland Medical School in the class of 1864.

Dr. Gustavus A. Doren, superintendent of the Ohio Institution for Feeble-minded youths, died at Columbus, on March 23, after a short illness. He was a graduate of the Berkshire Medical College, Pittsfield, Mass., in the class of 1859, and had been superintendent of the institution for over forty years.

Dr. William H. Warder died at Philadelphia on March 28, at the age of seventy-two years. He was born at Russellville, Ky., and was graduated from the University of Nashville in 1859. He went to Philadelphia in 1864 as a Southern refugee, and became associated with Jefferson Medical College as an extramural teacher, giving instruction to private classes in surgery and obstetrics. He was one of the obstetricians to the Philadelphia Hospital from 1874 to 1881, and he was a member of numerous medical societies.

Dr. George F. Leick of Cleveland, Ohio, and for several years head of the City Department of Health, died March 31, aged forty-nine years. He was a graduate of the Cleveland Medical College in the class of 1885.

Dr. Charles Wright Fuller died in Washington, D. C., on March 22, at the age of fifty-four years. He was born in London County, Va., and was graduated in medicine from the University of Maryland in the class of 1876. He practised for sixteen years in Baltimore and then removed to Washington.

Dr. Thomas C. Dolan died in Detroit on March 21, of renal tuberculosis. He was graduated from the Detroit College of Medicine in the class of 1904 and had been in practise in Lima, Ohio, for a few months only before his health broke down.

Dr. Horace Wardner died at La Porte, Ind., on March 22. He was a graduate of Rush Medical College, Chicago, in 1856, and served in the medical department of the Union Army during the Civil War. He was well known as an alienist.

Correspondence.

SECOND ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(From Our Special Correspondent.)

THE PHILIPPINES AS A PLACE OF RESIDENCE FOR THE WHITE MAN—MEDICAL PHASES OF IMMIGRATION LEGISLATION—DISPENSARY WORK IN MANILA—SCHOOL OF TROPICAL DISEASES

MANILA, P. I., March 4, 1905.

The second annual meeting of the Philippine Islands Medical Association, which began on the afternoon of March 1 at 4 P. M., was preceded by a function more or less social in character, which was held at the new government laboratory building on the evening of February 28. This building is now entirely completed and was thrown open on this occasion for the first time to the public for inspection. Fully a thousand persons were present, and for more than two hours many visitors thronged through the spacious corridors and the many different laboratories. The building was brilliantly lighted by electricity, which was made by the laborator's own electric plant. At about 9:30 P. M. the visitors were requested to assemble in the library, and in the presence of the Governor General, the Hon. Dean C. Worcester, Secretary of the Interior and head of the Department which exercises jurisdiction over the Bureau of Government Laboratories, delivered a short address. He stated that much misinformation had been circulated with regard to the building, especially to the effect that the cost of the building had been an enormous drain upon the resources of the government, the statement being often heard that the building had cost a half million dollars or more. This was not true because the actual cost had been under $108,000. He said that the Islands might feel proud of such an institution, in which so many kinds of both practical and theoretical experiments might be carried on. The institution, he said, was the most complete that existed in the outlying possession of any country, and compared favorably with similar institutions in Europe or America. From a practical standpoint it was of the greatest economical value, because experience had demonstrated that until science had come to the rescue the white race had never been able to inhabit the tropics successfully, and that much more work was required in this direction so that the danger might be still further reduced.

The first session took place in the library of the government laboratory. The program included an address of welcome by Governor-General Wright, but owing to his receipt of an important cablegram from Washington shortly before the hour of meeting, this duty devolved upon Commissioner Worcester. The meeting was called to order by the president, Dr. John R. McDill. An opening prayer was offered by His Grace the Archbishop of Manila, the Most Reverend J. J. Harty. Mr. Worcester in his short address to the delegates extended them a warm welcome in behalf of the chief executive and the insular government. He stated further that he was somewhat out of his element because he could not lay claim to being a doctor of any description unless the intricacies confronting an official of the Department of Interior could be deemed sufficient warrant for the bestowal of such title upon him. He referred to the condition existing in these islands by saying that the government is at present employed in an experiment in colonizing, and that a great deal had been accomplished, especially with regard to health conditions, which had made it possible for the white man to live in the tropics with almost the same security as he inhabited the temperate zone. Particularly was this true if excesses were avoided and a clean and moral life followed. Statistics of Manila showed that the death rate among the white race was 9¾ per cent. per thousand, while that of the natives was 53 per cent. The comparison was not absolutely fair, however, because many white persons on becoming ill immediately leave for the mother country, and thus many of the deaths which should be registered here are recorded elsewhere. He spoke of the provinces and the extensive travels he had made in them. He was often impressed with the lack of medical attention and was often distressed to see persons dying of diseases which would have yielded readily to medical or surgical aid, had it but been at hand. He said that even in Manila 50 per cent. of the deaths which were recorded occurred without the sufferer having had medical attention for the preceding illness.

Mr. Worcester was followed by Dr. John R. McDill, who delivered the president's annual address. He said that the medical men who came to the Philippines with the Army were the ones who had laid the foundation for medical research in the Islands. Our experience had been that with the exception of some intestinal disorders which we are rapidly preventing and curing there was nothing unusual about the amount or kind of disease encountered, and that its treatment was as successful as anywhere when hospital

care was available. For old people and children [illegible] an earthly elysium. Pride in the achievements of our insular Board of Health was shared by the public and the profession alike. He regretted to state that while every endeavor had been made to get the cooperation and the participation of the native physicians in the meetings of the medical society, thus far the efforts had met with very limited success. The Filipino medical students have two striking characteristics: (1) their astonishing capacity to absorb and expound theory, and (2) that the abler members of the profession have always been among the foremost political leaders of their country. The time when we could expect their cooperation would perhaps come only when the generation which is now being educated came to the front. He said that there were only 360 licensed physicians in the Islands, and that 217 of these were in Manila. These figures meant that while Manila had one physician for every 1,013 inhabitants, in the provinces there was only one physician for every 51,786 persons, or in other words, one doctor for each 430 square miles of territory. The whole hope for the medical future then lay in the establishment of a first-class medical school where the Filipinos might be properly educated. After this address the meeting was adjourned.

At 4 P. M., March 2, the Association again came to order. A paper on beriberi by Erwin Baelz, Emeritus Professor of Medicine, University of Tokio, was read by title only. The presiding officer, Dr. McDill, explained that Professor Baelz was prevented from coming owing to his services being required by the Mikado, who was ill. He said, however, that the paper would be published in the proceedings of the society. The next paper, "The Medical Phases of the Immigration Legislation," was read by Victor G. Heiser, P. A. Surgeon Public Health and Marine Hospital Service, Chief Quarantine Officer for the Philippine Islands. He stated that it was his intention to deal only with the medical features of the law, but that a brief résumé of the legislation might prove of interest. The various acts from that of 1819 to 1903 were briefly enumerated. It was not until 1882, however, that the medical aspect of the question had received any attention. In the law of 1903, however, the subject was rather fully covered, so that now the causes of rejection for medical reasons could be divided into two great classes: (1) those which are absolutely excludable, and (2) those which are likely to cause the alien to become a public charge. Under the head of those being absolutely excludable, trachoma was the disease for which the greatest number of rejections took place. He stated at length why this so-called minor disease received so much attention. Among other things, he said that 15 per cent. of the blind in the public institutions of the United States were there on account of trachoma. He also quoted from a letter received from the Health Commissioner of New York, which showed conclusively that trachoma was a serious disease from many standpoints, not among the least of which was the economic side. He also defended the placing of cases of tuberculosis in which the tubercle bacillus could be found in the sputum on the excludable list. He said that it was very communicable, that many of the immigrants would soon become public charges, that the United States could hardly be considered a charitable institution for the afflicted of other nations, and that the introduction of every case added just one more center of infection. Under the second class of causes which could be admitted by furnishing bond or other form of guarantee, were diseases like valvular disease of the heart. Such cases usually occurred in laborers, and after the strenuous exertion which was required in America there soon occurred a rupture of compensation, with the result that the victim became a public charge for many years. In short, any disease or deformity which would be likely to affect the immigrant's ability to earn a living would result in some sort of a guarantee being required before landing could take place. Another important result of the inspection was the detection of acute cases like typhoid fever, pneumonia, fractures, and other afflictions which would yield readily to treatment. Such cases were placed in the hospitals until they had recovered, at the expense of the transportation company bringing them. This one item alone [illegible] a saving annually of about $20,000 for each 100,000 immigrants that arrived. Whatever might be said to the application of the immigration laws to the Philippines as a whole, it was generally admitted that the application of [illegible] The natives are afflicted only to a very limited extent with trachoma, and to protect them from the virulent cases that occur among the immigrants that come to the Philippines [illegible]

[illegible] "Medical Care of the Indigent," was read by Dr. C. Radcliffe Johnson. He said that the diseases treated by him differed but little from those found among similar classes in the United States. The free medical attention was not nearly so much abused as in America. The greatest difficulty with which they had to contend was the fact that the native did not in most instances apply for treatment until the disease had progressed so far that relief was impossible. He thought that the large infant mortality was probably due to some extent to criminal abortion. He stated that they had many applications for abortifacients, and that much astonishment was expressed when they were not forthcoming.

The next paper was by D. M. Appel, Lieutenant-Colonel and Deputy Surgeon-General, U. S. Army, on "The Control of Tuberculosis." He treated the subject briefly and with particular regard to the disease as it is found in the Philippines. He thought the disease made more rapid progress here and more particularly in transients than in colder climates, but that it was not so prevalent as in the older and more civilized communities. Since the disease was due to lessened tissue resistance, such conditions as overcrowding, insufficient diet, poverty, etc., were the principal factors in its spread. The destruction of sputum was the best means of control. Lack of fresh air could not be ascribed as a cause because the natives nearly all lived in nipa houses and these it was impossible to close up in a manner so as to exclude the admission of air. Dr. Maximilian Herzog, in discussing the paper, stated that the two principal avenues of entrance were the alimentary and the respiratory tracts, and that therefore the best method of prevention was the destruction of sputum and the sterilization of milk—the former because it soon became dried, was pulverized, and blown about, and inhaled, and the second because it was taken raw, and was the food which was most likely to contain tubercle bacilli.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE GARCIA CELEBRATION—CLOSE OF DEBATE ON APPENDIX CASES—SCOTCH AND IRISH DIPLOMAS—VACCINATION AND GOVERNMENT—HOSPITALS AND COST OF MAINTENANCE—TROPICAL SCHOOL.

LONDON, March 17, 1905.

To-day we are celebrating the centenary of Señor Garcia. At noon addresses of congratulation on his reaching his one hundredth year were presented. Orders from the King of Spain and the German Emperor were first handed to him. Then followed addresses from our Royal Society, to whom his invention of the laryngoscope was first communicated; then from various academies, universities, laryngoscopical, musical, and scientific associations. The presentation of his portrait, painted by J. Sargent, R.A., and subscribed for by admirers in all civilized countries, closed the morning celebration. In the afternoon there was an exhibition of specimens, etc., by the Laryngoscopical Society. It was announced that the King had conferred the Victoria Order on the celebrated centenarian. In the evening the inevitable dinner comes off.

At the Medico-Chirurgical Society Mr. Harrison Cripps resumed the adjourned debate on the post-operative history of appendix cases. He drew attention to a cause of certain cases which has heretofore escaped notice. This is a twisting of the mesenteric attachment similar to that met with in some cases in the pedicle of ovarian tumors. He exhibited a model made of india rubber tubing attached to a piece of wash-leather, to show how the twisting occurred. If the twist were below the appendix got tucked under the cecum; if above the cecum appeared superficially. This twisting explains the sudden attack in these severe cases and the distorted, bent, and sometimes gangrenous state of the appendix. He had on two occasions been able to demonstrate the twist when operating. Very soon the pedicle becomes disguised by inflammation and adhesions, and can only be made out by careful dissection. The pedicle is no doubt sometimes cut through under the impression that it is an old adhesion. As it is universally admitted that suppuration or sloughing adds enormously to the risk of operation, it should not be delayed. He endorsed the views of Mr. Pearce Gould.

Dr. S. West spoke as a physician. He referred to the time when typhlitis and perityphlitis were regarded as medical and about 72 per cent. recovered without operation. Some cases recurred and could be operated on during quiescence. With signs of suppuration there must be no delay.

Mr. Bruce Clarke thought that in acute cases fatal results were generally due to infection of the peritoneum. In these he would not attempt to find or, unless it was easily seen or felt, remove the appendix. An operation could be performed without too great risk when the peritoneum was not fouled. If this seemed likely, it was safer to be content with evacuating the pus. In 191 out of 200 cases he found the epithelium denuded from inside the appendix, leading to septic invasion. In a recurrent case with additional signs abdominal section revealed a remarkable con-

dition, ileocolic intussusception and polypus at the end of the cecum.

Mr. Malcolm advocated early operations [illegible] some very insidious cases. He said a localized spontaneous gangrene in the appendix might cause a rupture, and referred to a case of Mr. Lockwood's in which such a patch was found with pus in the iliac fossa. Such a case demanded immediate operation as much as perfo[illegible] tric ulcer. But the diagnosis was so difficult that only a rule of early operations would save such cases.

Mr. F. C. Wallis would confine his remarks to two points not mentioned in the debate. One was the state of the omentum in acute cases. He had found it more than once infiltrated but not inflamed. It should be anchored or else removed, and he preferred the latter course. He described a case which led him to this practice. Three weeks after an operation for appendicitis the patient had signs of obstruction, and on abdominal section the omentum was found adherent to the small intestine in two places. His second point was a protest against letting the patient get up on the tenth or fourteenth day after excising the appendix.

Dr. Newton Pitt held that there has been a marked increase of appendicitis coinciding with that of influenza.

Mr. Mayo Robson sent a communication which was read by Mr. S. Paget. He held that with rigid asepsis the mortality should be nil in the quiescent stage, unless there were complications. Thrombosis might be due to keeping the patient too long in one position. He advocated separation of the muscles. He supported Mr. Pearce Gould's advocacy of early operation and removal of appendix when possible.

The President, Sir Douglas Powell, closed the three nights' important debate with some judicious observations on a few points brought out. He regretted Sir F. Treves was unable to be present and reply, and tendered the best thanks of the society to those who had taken part in the discussion, "which had been of an intensely interesting character."

Our Scotch and Irish brethren are again on the warpath. The Scottish diplomates have formed an association to enforce their rights to fill posts on hospital staffs in London. At their meeting there was much denunciation of the common regulation in London hospitals that the physicians and surgeons shall hold the diplomas of the London College. This of course renders Irish and Scotch graduates ineligible, but the assertion that the rules were made with that object is not correct, and nothing is to be gained by charging London men with selfishness and fear of competition on account of the regulation. The rule in fact comes down from the time when the qualifying bodies had territorial authority, and naturally candidates were required to possess the diplomas which were the only legitimate qualifications for practice. The abolition of territorial distinctions and the recognition of all the corporations as conferring equal rights to practice altered all this but did not lead hospital committees to revise their rules. The alleged exclusion of provincial qualifications is an accident, and the new association might very well appeal to the committees of hospitals to make a change, rather than spend their time in abuse and unjust charges. One of the speakers at the late meeting asked "Who keeps out the Scottish graduates?" and then roundly declared "They are the English diplomates and not the lay members of the hospital committees." The statement carries its own refutation to any one who knows anything about the matter, and will certainly do no good to the association. Nor is anything to be gained by comparisons of the standards of examination of the several colleges. One gentleman said as a teacher a man could pass the London College without dissecting a body. Certainly that is possible to some few men. As a teacher I have myself known of such a thing, but it is no more likely to occur at the London than at a Scotch college, and if such incidents are to be put forward as arguments, the retort will be that many a man having failed in London has taken train to Edinburgh and returned with a diploma. In the vast majority of cases a man qualifies where he was educated, and this resolves itself into the accident of residence. The first qualification he takes only certifies his fitness to practice, and it is nonsense to talk of the state being deprived of the gift of genius through this grievance of Scotch and Irish doctors. After all, the staffs of the London hospitals number but few in comparison with the mass of practitioners, and it would be impossible to find a post for every Scotch or Irish doctor who, having qualified at home, comes to London to try his fortune.

The Anti-Vaccination League held its annual meeting on Wednesday with a Lieutenant-General in the chair, and letters of sympathy were read from a duke, two earls, and two ladies. That does not seem a very powerful assembly, from a scientific or any other aspect, but it announced positively that sanitation is a true preventive of smallpox, and it was sure to abolish vaccination in time. As far as the present government is concerned, this may very well be; for the promise to introduce a revaccination bill has not only been broken up to t[illegible] told there is no intention of doing so this session. A bill has also been introduced into th[illegible] which has no chance of passing, but is merely a bid for the votes of the fanatics by this jelly-fish government.

Some curious statements have been [illegible] newspapers as to the expenditure in Scottish and English hospitals. Differences in diet, the price of food, and other points were raised. The superintendent of the Edinburgh Infirmary has compared the prices paid in that institution with those of the London Hospital, and reports that: Meat in 1904 cost a fraction over 6½d. per lb. for home fed, as compared with 5d. for foreign meats in London. If the Edinburgh Hospital had bought meat at 5d., it would have saved £1,163 in the year. Milk in the same way would, if it could have been bought at the London price, have cost £485 less. Six articles given to Edinburgh patients, but not in the London Hospital, account for £11,152, or 69 per cent., on the food expenditure.

In 1903 the cost of provisions per head in the London Hospital is put at £31 5s.; in the Infirmary, at £20 11s. 8d. In 1904 the Infirmary paid £273 in pensions and £226 in window cleaning. If an investigation of the cost of the out-patients in London were made it would probably give more startling figures.

The Princess Christian has accepted the presidency of the Royal Maternity Charity, a post which has been vacant since the death of the late Duke of Argyll. On Wednesday the Princess presided at the annual meeting of the Royal Free Hospital and inaugurated the new additions.

Mr. Tweedy, F.R.C.S., presided at the annual meeting of the Royal Dental Hospital, on Tuesday, and testified to the progress of dental surgery and the good work of the hospital and school. Both hospital and school owe much of their prosperity to the dean, Mr. Morton Smale, who has lately resigned, after twenty years' service, during which the progress of the institutions has been uninterrupted.

The University of London has admitted the School of Tropical Medicine as a school of the university, and decided to make the subject one in which candidates may proceed to the M.D.

Professor McHardy presided at the Royal Eye Hospital, Southwark, and said 652 in-patients were treated during the year, and 1,250 accidents and urgent cases. Money is wanted for repairs, etc. The expenditure was £3,601, and, wonderful to relate, the deficit only £13.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

ORIGIN OF COLOSTRUM CORPUSCLES—CHEMISTRY OF THE GASTRIC JUICE AND ATONY OF THE STOMACH—TRYPANOSOMES IN SLEEPING SICKNESS—MECHANISM OF LABOR.

VIENNA, February 28, 1905.

At a meeting of the Society of Internal Medecine, Popper presented a paper on the origin of the colostrum corpuscles. As is well known, these are found in large numbers in the breasts after lactation has ceased. Czerny, as the result of his experiments on frogs, arrived at the conclusion that the colostrum corpuscles are emigrated leucocytes that have taken up fat. Popper contested this view and demonstrated that the bodies in question have nothing to do with leucocytes, as they are degenerated epithelial cells which desquamate into the lumina of the glands. The following facts confirm this standpoint. The colostrum corpuscles have a characteristic epithelial vesicular nucleus which is of a type not occurring in any variety of leucocyte, but which is normal for the mammary epithelia. Experiments on frogs and rabbits showed that although after taking up fat leucocytes may enlarge and somewhat resemble colostrum corpuscles, their nuclei never change in form and always retain the characteristic leucocytic appearance. Experimental fatty degeneration in female breasts causes some of the epithelial cells to change into colostrum corpuscles, as may be observed in microscopical preparations. The ameboid motility of the colostrum corpuscles, which was interpreted by Czerny as being evidence of their leucocytic origin cannot be assumed to have this significance, for it has been shown, especially by recent work, that this faculty is not a prerogative of the leucocytes alone, but that all other animal cells, such as connective tissue cells, epithelial cells, etc., may exhibit it if they are set free from their tissue connections. Besides, it is only the smaller colostrum corpuscles that are motile, and the phenomenon has never been observed in the larger cells. Popper also cites the fact that in pregnant animals the mammary acini are greatly increased in number, while at the close of lactation there is a gradual disappearance of the glandular elements, which, according to analogies in other organs, would most naturally occur through fatty degeneration followed by desquamation and absorption.

R. Kaufmann addressed the same society on atony of the

stomach and the chemistry of the gastric juice. According to the usual statements in the literature the total acidity of the healthy stomach after a test meal varies between 30 and 60, and the free hydrochloric acid between 0.07 and 1.5. Kaufmann examined twenty-two healthy individuals and in two cases found achylia, in three cases absence of free hydrochloric acid, and in eighty a total acidity below 60, in nine about 60. The highest values were 80 to 100, and the free hydrochloric acid ranged from 0 to 3. It is therefore incorrect to assume that in health the total acidity is restricted to the narrow limits ordinarily given. The symptoms of patients suffering from hyperacidity or subacidity are ascribed to the corresponding abnormality of gastric acidity. On analyzing the gastric contents of twenty cases of hyperacidity the following values were obtained: In four cases over 90, in half the cases under 80, in one-third under 70; the free hydrochloric acid was in nine cases under 1.5, and the highest figure was 24. Therefore the degree of gastric acidity of patients complaining of the usual symptoms of pain several hours after meals, painful hunger, acid eructations, vomiting of acid material, etc., was by no means greater than in healthy persons, and could therefore not be the sole cause of the symptoms, especially as the total acidity remained unchanged after a cure had been effected. Similar conditions were observed in fifteen cases of subacidity. Here, again, values corresponding to the normal ones were obtained. The gastric disturbances must therefore be due to some other factor, which in Kaufmann's cases usually appeared to be atony, as could be demonstrated by inflation of the stomach and radiography. In some cases general neurasthenia or some anatomical lesion, such as ulcer, was concerned. Proof of the correctness of the view ascribing the major portion of the responsibility to gastric atony is to be found in the fact that after recovery the acidity remained unaltered but the atony had disappeared.

Trypanosomes as the cause of sleeping sickness were discussed by v. Steinitzer. Trypanosomiasis in animals ordinarily takes the form of cachexia, fever, anemia, indurations of the skin, falling of the hair, paralysis of the extremities, and swelling of the spleen and glands. Human infections are commonest among the natives of Central Africa, though European residents of the regions are not immune. The patients at first show cutaneous rashes and splenic swelling, which may form the only symptoms for some years. With the onset of the second stage, dizziness, backache, and the other manifestations of sleeping sickness set in, as shown by apathy, anemia, muscular weakness, refusal of nourishment, and death at the end of several months. On the injection of nagana trypanosomes into mice, the parasites may be detected in the blood on the second day, and they finally multiply to such a degree that they outnumber the red blood cells so that the animals die through the vascular obstruction caused. In sleeping sickness, however, in spite of the severe symptoms, no parasites are to be found in the blood, and the condition has been held to be produced by toxins, though none have as yet been isolated. Not all of the experimentally infected animals perish, as some acquire an active immunity. If pathogenic trypanosomes are injected into such immune animals the parasites may be found in the blood in a severely damaged condition, without flagella, and with rounded ends, and finally they are completely digested, apparently through a sort of phagocytosis. Orrhotherapy has not been effectual in combating the disease, and of the chemical remedies quinine has no action on trypanosomes in the living body, although in the test tube it has some effect. Better results follow the use of arsenous acid in combination with the dye, trypan red, and also with malachite green, which does not cure the disease, but does prolong its course. Isolation and hygienic precautions are the only means of prophylaxis at present.

Professor Herfeld delivered an address on the mechanism of labor before the Society of Physicians, illustrating his points by means of the ingenious models and manikins devised by Professor Sellheim. The entire mechanism of labor may be explained on purely physical grounds. In order to illustrate the internal rotation of the fetal head, two cylinders were used, one of which could be bent in two directions at right angles to each other, and the other one only in one direction. If such cylinders are fixed in a frame and a force is caused to act on them in the direction of their flexibility they bend without rotation. If, however, the force acts in an axis opposed to that in which the cylinder is flexible the peculiar phenomenon of rotation appears. The cylinder turns about its long axis until the direction of its flexibility corresponds to that of the force. The results of this experiment in physics may be transferred to the rotation of the fetal head. At the pelvic inlet the head has its long axis in the transverse pelvic diameter. The birth canal is not cylindrical, for the greatest diameter at the inlet is at right angles to the greatest diameter at the outlet. As the head is being driven downward by the action of the uterine musculature, it rotates about its axis until at the outlet its largest diameter corresponds to that of the outlet. Two of Sellheim's manikins were also shown. These were constructed to illustrate the principles of the child's vertebral column, which in the cervical portion most easily bends backward, in the thoracic portion bends laterally with ease but with difficulty backward or forward, etc. The manikins slide along a path corresponding to the axis of the parturient canal and are provided with weights to simulate the flexor and extensor tendencies of the fetus. The experiment shows that the vertebral column in its passage downward always places itself so that its line of greatest flexibility follows the curve of the canal. The apparatus serves to explain the mechanical factors present in any of the fetal positions.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 30, 1905.

Angioneurotic Edema.—F. B. Harrington reports a case operated on during an abdominal crisis, giving at the same time a general description of the disease. His patient was a single woman of 26 years, whose initial symptoms were strongly suggestive of gallstones. Fifteen years before she began to have attacks of swelling in the hands. As she grew older the attacks became less frequent, but during the last few years they had occurred as often as every two weeks and were not confined to the hands alone, but reached to the elbows and involved the feet. Less often the face was involved. Various areas of the trunk were also affected. Finally the attacks of abdominal colic appeared, and one in particular was so severe that exploratory laparotomy was considered justifiable. The only abnormality found was an engorgement of the bowels with blood. There were no hemorrhagic areas in the intestinal walls, but at a point within a short distance of the ileocecal valve, a cylindrical enlargement of the ileum 2½ inches long was brought to light which entirely surrounded the gut, increasing the bowel circumference to twice its ordinary size. The swelling was evidently in the bowel wall, elastic to touch and did not pit upon pressure. It can be easily understood how such an infiltration could derange peristaltic action of the intestine. The lower border of the stomach was about half an inch below the umbilicus, and the pylorus admitted the tip of the index finger. The appendix seemed somewhat thickened and was removed, but at examination it was found to be normal. The engorgement of the intestines and the free fluid were explained by the violent peristalsis brought on in the effort to force down the lesion which was actually in the intestinal wall. There was no distention above the lesion since the finger could be easily passed into the swelling at either end. She had a comfortable convalescence, though some colic attended the first movement of the bowels after operation. An attack of skin swelling came on before her discharge, but otherwise she has not suffered any unpleasant sequelæ.

New York Medical Journal, April 1, 1905.

Recent Advances in Electrotherapeutics.—The special topics considered by W. J. Morton are the Röntgen ray, radium, and artificial fluorescence of living tissues. The *x*-ray has greatly increased the percentage of cure in cancer. Superficial growths are most likely to be permanently cured. Not much has been done for the disease when located in internal organs. Some cases of gastric cancer may be cured if the growth is of a superficial type. The same statement holds true of some cases in the upper respiratory region. Some cases of uterine disease have been cured, while the progress of many has been retarded. The same general statements may be made with regard to radium. Concerning both, it may be said that they ought to be used both before and after operation. With regard to the fluorescence of living tissues, the author has used quinine, asculin, and fluorescein, the latter being particularly good, owing to its non-toxic properties. He uses this method for tuberculosis, tupus, tuberculous glands, etc. Cases of chronic malaria have not been benefited. In one case of ameba coli, in which two abscesses had been opened, and in which it had been proposed, in order to stop the progress of the disease, to open the colon and inject ice-water, the microorganisms have been completely destroyed. Morton also notes that if we administer to a patient twenty drops of an aqueous solution of fluorescein, one part of fluorescein to thirty of water, and, say, forty minutes later on, make an *x*-ray exposure to a photographic plate, we obtain a radiograph of superior contrast and definition. In a similar manner, fluorescopic examination of this patient, particularly of the thorax in tuberculosis of the lungs, is greatly aided.

The Management of Pneumonia in Infants and Children.—C. G. Kerley says that in dealing with pneumonia we are handling a disease we cannot *cure*. Our efforts

must be confined to placing the patient in the best possible condition to resist the infection and wear out its effects on the system. A sick-room régime should be established with just as much definiteness as the surgeon uses in a major operation. Special attention must be given to details of ventilation, diet, quiet, and clothing. He has no special drug treatment to suggest. The indication for relief of high temperatures is found in their effect on the patient rather than by the reading of the thermometer. Detailed directions are given for the use of the pack. This need not necessarily be cold, or even cool. It may be begun with water at 90°. For cardiac stimulants, strychnine and strophanthus are found preferable to digitalis and the ammonium salts. The heavy expectorant syrups are avoided. In the bronchopneumonia of babies we may get good effects from inhalations, counter-irritation, and to a less degree from expectorants. As between the two common types of pneumonia, we have to remember that in lobar pneumonia we have a self-limited disease. We prepare the way and place the patient in the best position to resist, to take care of the infection. We endeavor to preserve his vital powers; and Nature, if she is kind, brings about a favorable termination. In bronchopneumonia we must perform all of these offices and more. Bronchopneumonia in babies does not possess the characteristic of self-limitation. In this type in babies there are measures as above suggested which directly assist in controlling the progress of the disease.

Medical News, April 1, 1905.

Nephritis Complicating Mumps.—J. A. Miller calls attention to the lack of definite literature upon this complication of mumps. He reports one case the features of which are summarized as follows: A case of acute exudative nephritis in the course of mild double parotitis, in a boy four years old, with a marked family predisposition to kidney disease, occurring in the twelfth day of the parotitis, which was further complicated on the eighteenth day by a moderately severe attack of measles. The measles exercised no influence upon the nephritis, which entirely disappeared in thirty-five days, and after several months had not recurred. A careful review of the literature has revealed reports of twenty-nine similar cases. In addition to these, several observers mention the occurrence of febrile albuminuria during mumps as not infrequent. The author presents the following conclusions: (1) Acute nephritis complicating mumps may occur in either children or adults, and is much more frequent in males than in females. (2) The parotitis is usually double, mild in character, and the nephritis is more liable to occur during early convalescence. Exposure to cold may be a predisposing factor. (3) The nephritis is usually moderately severe, of less than one week's duration, and ending in complete recovery. Rarely it may develop into chronic nephritis, or it may be so severe as to cause death. (4) This complication of mumps is infrequent, but probably not as rare as usually considered. Febrile albuminuria is probably very common in mumps, but this, as well as more serious kidney lesions, is probably often overlooked. (5) Careful urine examinations should be made, and strict precautions against exposure should be taken, in all cases of mumps, both during the acute symptoms and during convalescence.

The "Specific Therapy of Tuberculosis."—The paper of C. F. Denison is a general discussion of Professor Maragliano's recent address before the Henry Phipps Institute. He inquires, "Has the indirect serum method any advantage over the direct toxin method?" inclining to the latter when properly selected with refined technique both as to quality and dosage. He criticises the Italian professor as making much of the effects of the toxins of young cultures of bacilli in their inflammatory and destructive action in the tissues with which they come in contact. This is considered as due to the "necrotic acid" of certain authors. Denison asks concerning this acid, "What is is? and how much of it is necessary to produce the effects stated?" With reference to Maragliano's claim of a "double series of poisons"—the bacilli and the accompanying proterns. Denison asks if it is to be inferred that Maragliano claims such a mixed toxin is always used in the direct method? His own view is that success comes through the singleness and purity of the toxin used. He finds no warrant for expecting any better effect from the antitoxin previously developed in another animal over and above that slowly created in a given diseased organism. His own experience with the crude tuberculin test is to the effect that he has proved latent tuberculosis to exist in forty-seven out of fifty-three cases in which there was either no sputum to examine or only glandular or other suspicions of infection. Let us assume, he says, that there has been an advance possibly of 20 to 40 per cent. more of the course of the disease by the time the "mixed infection" period determines a still further stage in this process of decay. What is going on . . . constant battle between susceptibility and resistance to this toxic influence. If we were able to determine the faults of our civilization, which [illegible] this [illegible], we could better understand the character of this conflict; for then we would comprehend that this disease, tuberculosis, is but a natural harvest from such degenerate soil.

American Medicine, April 1, 1905.

Treatment of Cerebrospinal Fever.—Charles G. Stockton emphasizes the importance of bringing about the best hygienic condition for the patient. This is accomplished by the absolute quiet in well-ventilated, darkened rooms, with the absence of all excitement and irritation. Giving the greatest attention to secure the proper performance of the various functions of the body. The trial of the hot baths after the method of Aufrecht in all cases in which they seem to do good. The practice of intraspinal puncture, with drainage when necessary to relieve severe pressure symptoms, to be repeated, if necessary, provided benefit follows the first puncture. The use of antipyrin in cases in which the temperature is raised not only for the relief of this symptom, but for the mitigation of headache and hyperesthesia. Dr. Stockton has found this drug also useful in improving the mental state, and in his hands it has not been followed by the expected depression. The use of opium or the bromids alone, or in connection with antipyrin, if necessary, for the relief of convulsions, pain, hyperesthesia and pressure symptoms generally, which are not relieved by the foregoing methods of treatment. The use of mercury when needed for its laxative effect, or when needed to assist in stimulating the organs of elimination opium and the bromids are indispensable in some cases and large doses are at times necessary.

Temperament, Diathesis, Dyscrasia, Predisposition, Cachexia, Susceptibility, Idiosyncrasy, and Heredity.—Homer Wakefield begins his article in a previous issue with a review, descriptive and critical, of temperament, diathesis, dyscrasia, predisposition, idiosyncrasy, susceptibility, cachexia, and heredity. Then follows the author's proposed division of the diathesis, which he has arranged in a definite order of succession and correlated to the stage manifestations of the retrogressive degeneration of catabolic stasis, and the latter again to the expression stages of the retrograde metamorphosis of such rudimentary forms of life as naked unicellular organisms, which he has characterized as the "biologic series." Clinical illustrations and quotations supplement his premises. Predominant clinical manifestations are duly classified in definite order of succession, and he shows that symptomatological and morphological manifestations of disease are but expressions of different stages of one homogenic retrograde metamorphosis, which he holds to be universally due to and dependent upon some type of factor of a stasis of catabolism. Of unusual interest and importance is his contention that protoplasm, both of unicellular life and of the parenchyma of the higher animals, attains density in proportion to normal cell maturity and suffers expansion and elongation in ratio to its subcatabolism. Wakefield analyzes separately the several predisposing and exciting etiological factors, commonly met clinically, and points out the homogeneity of their pathogenic actions, and how they operate and cooperate to produce a common pathogenic action, namely catabolic stasis. Susceptibility to parasitic infection is attributed to tissue atony and the morphological changes of subcatabolism, and he illustrates the dependency upon etiological factors as catabolic stasis. Heredity he defines as substantially a congenital structural expression, and he denies that diseases are specifically inherited, but instead an adaptation of metabolic equilibrium obtains as governed by the transmitted capacity for oxidation, etc.

Peritoneal Adhesions.—Carl Beck says the study of adhesions forming after repeated attacks of appendicitis has also given us clearer insight into adhesion formations in general, revealing many obscure ailments in their true light. Adhesions are found more frequently in the ileocecal region than anywhere else. As a rule there is a broad parietal adhesion especially if there is postoperative hernia. The peristalsis of the free part of the gut elongates it until it becomes a tense, unyielding band; and if an intestinal loop becomes ensnared below it, its circulation will be under pressure, and will give rise to more or less disturbance, sometimes even to complete strangulation, especially if there is procrastination. After early operation postoperative adhesions are rarely found; another point in favor of prompt early surgical interference in appendicitis. Beck's experience in cases of chronic progressive adhesion-forming peritonitis, as observed idiopathically as well as after appendicitis, is absolutely bad. The nature of this peculiar condition, characterized by a multitude of cobweb-shaped bands, is not yet sufficiently elucidated.

Journal of the American Medical Association, April 1, 1905.

Acute Meningitis.—W. T. Councilman describes the conditions of acute meningitis with more special reference to that form produced by the *Diplococcus intracellularis men-*

ingitidis, which he believes is constantly occurring in a sporadic form, aside from the not infrequent epidemic aggravations. The infecting organism, he states, is one of low vitality and incapable of a purely saprophytic existence. The statistics fail to give any adequate idea of the frequency of the infection in ordinary years. His experience, however, leads him to believe that with rare exceptions all cases of primary meningitis are due to this microorganism and that it would be impossible without sporadic infections to bridge over the intervals between the epidemics. It is possible, too, that the germ may even inhabit the normal mucous membranes of the nose, for example, as has been shown in a few cases, where it produces a rhinitis, and infection of the meninges may take place through the lymphatics or by continuity of surface. We can only explain the epidemics of the disease, he says, either by an increase of virulence of the diplococcus or by a decrease in the resistance of the tissues. The underlying causes of epidemics are unknown, and even atmospheric conditions can not be excluded. He discusses to some extent the relations of meningitis to pneumonia, as shown by the Massachusetts health statistics, and illustrates with a chart. Primary meningitis from the pneumococcus or staphylococcus is rare; secondary types are not so infrequent. The paper concludes with a description of the pathologic conditions in acute meningeal disease.

The Therapeutic Use of Fluorescence in the Human Organism.—W. J. Morton discusses the production of fluorescence in the tissues of the human organism by use of fluorescing solutions, electricity, etc. He holds that it is a sort of phototherapy dependent on the same principles for its curative effects. The method includes filling cavities with fluorescent solutions as well as using these latter medicinally. It produces effects by the fluorescent excitation of the absorbed drugs, not due to the *x*-ray or to radium, but probably to the fluorescent light. What the latter lacks in intensity is compensated for by its propinquity to the tissue. It is also possible by this method to improve skiagraphic effects and fluoroscopic examinations. It has proved of value in determining the position and size of the stomach and other cavities of the body. By this means the thoracic cavity is illuminated on the fluoroscope far more than it can be by the *x*-ray alone. Morton has found it therapeutically useful in pulmonary tuberculosis, as well as in local tuberculosis elsewhere, and especially in cancer, of which two successful cases are reported.

Typhoid Perforation.—Morris Manges reports nineteen cases of perforation in typhoid, with sixteen operations and five recoveries. He discusses the subject generally, but emphasizes particularly the diagnostic significance of pain, which under certain conditions in this disease may accompany non-perforative peritonitis. He considers that the most important facts in the diagnosis are the marked change in the patient's condition with the abdominal pain, which is very variable, and that the other abdominal conditions, distension, rigidity, tenderness, liver dullness, etc., with the anxious facies and sweating, are valuable aids in the diagnosis. Changes in the rate and character of the pulse are of more value than temperature or respiration. Manges believes in the occasional spontaneous cure of this condition, and refers to one case in his series in which this apparently occurred, and to another, in which, at the autopsy, a small perforation was found well sealed by omentum. The rule to operate, however, is not vitiated by these rare occurrences, and operation itself does not add to the dangers and may be effective in preventing a perforation where one is not found.

The Lancet, March 18, 1905.

The Nature and Treatment of Epilepsy.—A general review of the subject is given by W. A. Turner, nothing new being brought out. He does not believe that any definite statements can yet be made with reference to the toxicity of the urine in epilepsy, for different observers have obtained quite different results. As regards the reaction of the blood, the general conclusion is that, prior to a convulsive attack, there is adminished alkalinity, but whether this arises from retention of uric or carbonic acids, or from acid toxins of undetermined composition, remains undecided. Treatment is of a far wider significance than the mere subduing of convulsions by drugs. The child with epileptic tendencies must be educated along the modern lines, which have proved so successful. Bromides, while not the only remedy at our disposal, probably do more good than any other single remedy. The author has not had much success with bromipin. Bromocarpin is recommended, he says, in those seizures which seem to result from intestinal autointoxication. Borax and digitalis combined are of service in some minor cases. Belladonna will often succeed where bromides have utterly failed. Organotherapy has thus far proved a failure. Immunization is a delusion. The author advocates the "salt starvation" plan as an advisable dietetic feature.

Mental Faculty in the Child; Its Growth and Culture.—F. Warner notes that two phenomena are characteristic of the earlier workings of the brain, spontaneity and controllability. By the interaction of these, the brain cells are coordinated through the senses by suitable methods of training. As the child develops, we endeavor to produce a new impression and after frequent repetitions of the impressions some are retained. Two points are insisted upon: (1) A certain length of time is required for the production of a new impression in the brain since a definite period is required for the arrangement of the nerve centers under control and (2) physiological impressions on the brain may be of different kinds as produced by various modes of external sensory stimulation. Thus we may have impressions of sight, of hearing, from muscular action or by muscular tension. Only one kind of impression should be taught at one time. Another way of teaching is by imitation. Impressions made on the brain must be associated with intellectual purposes. Impressions of similar sensory origin more readily adhere to one another in the brain than those of different classes. The similarity in their modes of production by sight, hearing, muscular sense, etc., and their consequent similarity in constitution cause them to be easily associated when rendered reactive under the guidance of the teacher. Nerve pathways are more easily established among like sensory impressions than among those unlike in kind. In an act of comparison we need the coactivity of two or more impressions of the same kind; a mental act of comparison is appreciation of the similarity of characters and their proportions.. If the pupil had received stage by stage the early elementary training already described his brain will by this means have been prepared for mental work and he will more readily and accurately appreciate instruction such as the relative weight of coins and their value, also the significance of addition, subtraction, multiplication, and proportion

The Lancet, March 25, 1905.

A Note on the Abdominal Incisions for the Exploration of the Appendix and Perforated Ulcer of the Stomach.—Cuthbert S. Wallace describes an incision which he believes combines some of the advantages of both that of McBurney and that through the rectus sheath. The rectus sheath is entered towards its outer side by the usual vertical incision. The muscle is then retracted inward and the posterior wall of the sheath is exposed. As a rule two nerves are seen running transversely inward about one inch apart. The mid-point between these is selected and the peritoneal cavity is entered by an incision one inch long transverse to the body axis and parallel to the nerves. This incision is easily closed, since the natural tension of the parts approximates the edges. Should difficulties be encountered in the removal of the appendix and a large incision be required, it can be obtained by the usual vertical incision in the posterior rectus sheath. In order to decide whether the pelvis has become infected or not, in perforating ulcer of the stomach, an incision must be made in the hypogastrium. If this is made after the upper incision, there is danger of infecting the pelvis if this is clean. It seems advisable, then, to make the hypogastric incision first in cases of doubt. If the pelvis is clean, the wound can be closed. If the contrary proves true, the lower wound can be used in the process of cleansing the peritoneum. The primary lower incision is also of service in determining the condition of the appendix when there is doubt as to whether the appendix region or the upper part of the intestinal tract is at fault.

Relation of the Parasitic Protozoa to Each Other and to Human Disease.—E. J. McWheeney, in speaking of the disease-producing protozoa, declares that they reveal a surprising complexity of reproductive phenomena, and an equally surprising parallelism in the developmental cycle of forms which at first sight seem far removed. The protozoa or one-cell animals are divided into four classes: the rhizopods, the sporozoa, the flagellates, and the infusorians. The rhizopods comprise mainly amœbæ. The amœbæ are the ones of particular interest. Some amobæ have a shell and some are naked. At least one of the former and two of the latter sort are known to occur in the intestine. The two naked forms are genuine parasites. One of them is harmless—the entamœba coli. The entamœba histolytica, amœba dysenteriæ, is pathogenic. Its tough ectoplasm enables it to force its way into the deeped layers of the mucous membrane where it multiplies and forms the undetermined ulcers so characteristic of tropical dysentery. The spore-containing feces of cases of dysentery must be prevented from getting access to drinking water or from being conveyed by flies and deposited on food. Among the chief orders of the sporozoa are the hæmosporida or parasites of the blood corpuscles, which are the cause of malaria. The intermediate host of blood-inhabiting parasites is an invertebrate bloodsucker. The writer finally discusses the order of the flagellates, to which belong the trypanosomes. Recently, the rôle of these parasites as disease producers among the lower animals has been greatly enlarged. In

1903 a trypanosome was discovered in the cerebro-spinal fluid of natives of Uganda affected with sleeping sickness. In smears of spleen pulp from cases of splenic cachexia in India, parasites have been discovered which have been shown to be stages in the development of a trypanosome. Rogers has discovered that blood containing Leischman-Donovan bodies gives rise to trypanosomes. Kala-azar and cachexial fever will doubtless prove to be a form of human trypanosomiasis. The same will probably hold true of the bodies found in the granulation tissue of Delhi boil and tropical ulcer.

Premenstrual Pregnancy in a Girl Aged 13 Years.—Augustus W. Addinsell reports this case, the interest of which lies in the fact that impregnation took place before the outward signs of sexual maturity had manifested themselves. It is quite certain that menstruation had never occurred. In premenstrual life, maturity up to a point is constantly going on in the follicles of the ovum which come to the surface, and when that point is reached retrograde changes take place in the infantile ovary. As the age of sexual maturity is being reached and as ovulation is regularly proceeding, it is easy to see how impregnation might occur even though the outward and visible signs of sexual maturity be absent. The periodic occurrence of ovulation is independent of menstruation, and precedes its initial onset. It is easy to see how the nervous and circulatory excitement attendant upon the act of coition might bring about the rupture of a ripe follicle and the resulting escape of the ovum.

British Medical Journal, March 18, 1905.

Some Remarks on Puerperal Infection.—Arnold W. W. Lea compares the frequency of infection as it occurs in surgical practice and in midwifery. In the former it has been almost abolished, but this cannot be said in regard to the latter. All manipulations in relation to the woman in labor require those precautions which are taken before a surgical operation. The essential points are largely included in the words "surgical cleanliness." It is not possible to obtain exact figures of the morbidity rate in private practice. Puerperal fever is a wound infection. After labor, the uterus forms a vast and irregular wound surface deprived of epithelium and presenting many openings of vessels, an area peculiarly favorable to the stagnation and absorption of septic products. The uterine mucosa is not protected from infection for ten days after labor, and for nearly three weeks the mucous membrane is very thin and soft, readily becoming an absorbing surface if injured in any way. The essential feature of the disease is a microbic invasion. Although many organisms may produce it, practically a few only are of great importance. Streptococcus pyogenes is the organism most often found. Its invasion of the uterus is frequently characterized by grey membranous exudation over the cervix. The lochia are as a rule profuse, hemorrhagic, and not offensive. They may in severe cases be diminished or even suppressed. Staphylococcus pyogenes, albus, and aureus are often present in puerperal infection. They are frequently saprophytic, but they may rarely cause even fatal infection. Bacterium coli commune is a frequent cause for infection. Its virulence is increased when it is associated with streptococci. The infection is characterized by very offensive lochia. The clinical course of the disease depends upon many factors, such as the period at which infection occurs; the site of infection; the type of organism and its virulence; the local conditions present in the uterus, and the resisting power of the individual. The prompt recognition of infection is important, for at this time treatment may radically change the course of the disease. The early signs are few but definite, and include the following: Rise of temperature, increase of pulse-rate, delayed involution of the uterus, and changes in the lochia which are not uniform. The only reliable method of investigating the lochia is the bacteriological one. The prognosis must always be guarded. Although there is a general agreement as to methods of prevention, as well as to the necessity for supporting measures in cases of puerperal sepsis, there are still grave differences as to the best methods of local treatment. The writer describes his own method, which is based upon notes of 120 cases, as follows: A rise of temperature of 101°, not accounted for by other causes, renders a careful examination of the generative tract necessary. If no sufficient cause is found in the vagina or perineum, and if the uterus is bulky and tender, a specimen of lochia is removed and a uterine douche given with due precautions. The interior of the uterus is then swabbed with absorbent wool soaked in a solution of biniodide of mercury in alcohol, 1 to 2,000. This removes tissue shreds and blood clot. If this does not suffice, or if the infection is from the first severe, the uterus is explored with the fingers, preferably under chloroform. If the cavity is perfectly smooth, which is not often the case, the uterus should be thoroughly swabbed out with the biniodide in alcohol or some strong antiseptic solution, and packed with idoform gauze soaked in an antiseptic. If a piece of placenta is found, it should be taken away together with the blood clots, followed by swabbing and gauze packing. If the cavity is enlarged and the surface irregular, due to hypertrophied and necrotic recidua, the patient's safety can be ensured only by its complete removal. This is best done by the use of a suitable curette. There has been much discussion as to the use of the curette in the pureperal uterus. Posterior vaginal section may be carried out as supplementary to curettage if symptoms of pelvic peritonitis are present. The operation of hysterectomy has been performed in 137 published cases with a mortality of 63 per cent. As to the use of antistreptococcic serum, the serum is [illegible] and injected with due precaution. It must be given early in the disease, and in large doses—20 c.c. twice or thrice in 24 hours in severe cases. If given in this way, definite improvement is observed in a considerable number of cases. It would seem from reported results that serum should be given in all severe infections.

An Unusual Complication of Varicella.—Carey Coombs describes a severe attack of chicken-pox in a boy of eleven years. Two days after the disease first showed itself, the physician was called to his relief. The boy had passed practically no urine for sixteen hours, and was in pain with constant but ineffectual efforts at micturition. The prepuce was swollen, and its opening obliterated by a large pock, and within the urethra, half an inch from the meatus, was a very tender and painful spot. The boy was given a hot bath and a full dose of morphine, which was almost immediately followed by a plentiful passage of urine. The case cleared up with no further complications. The writer believes that this is a rare incident.

British Medical Journal, March 25, 1905.

Transillumination of the Antrum of Highmore.—A. Brown Kelly points out that in practising transillumination, a fallacy may arise in one of three ways: (1) The light may shine with equal brilliancy on both sides, though one antrum contains pus while the other does not. In such a case the amount of pus is usually very scanty and the antral lining but little thickened. Too strong a light is apt to produce this fallacy, which is more apt to occur if the pus is of dental or extra-antral origin. (2) Transillumination may be bright on one side and darker or absent on the other, and yet on the non-illuminated side pus may be absent. The unilateral shadow may be due to either abnormal thickness of the bony walls, small size of the cavity, thickened lining from previous disease, solid tumor, or obstruction of the corresponding nasal fossa. (3) Both antra may light up badly or not at all, and yet contain no pus. This may be due to too weak a light, thick bones, high palate, or obstructed nasal cavities.

The Opening of Peritonsillar Abscesses.—According to St. Clair Thomson the point of election for the opening of a quinsy is just external to the junction of a transverse line across the soft palate just above the base of the uvula, with a vertical line drawn to meet the one just located from the lower part of the anterior pillar on the affected side. The preferable instrument for making the opening is a modified Lister's sinus forceps. The extremity is sufficiently blunt not to injure healthy surfaces but is fine enough to allow of its being pushed through edematous necrotic or membranous tissues. The point above named corresponds to the supratonsillar fossa.

Berliner klinische Wochenschrift, March 13, 1905.

A Hitherto Undescribed Phenomenon in Peroneal Palsies.—Hirschfeld in examining eleven cases of this affection observed a peculiarity affecting the power of dorsal flexion of the foot. Five of the cases were of peripheral palsy, including three instances of multiple neuritis, and of the others two were of myelitic and four of hemiplegic origin. In studying the patient's muscular control it was found that with the knee extended the ability to flex the foot dorsally was much less than when the leg was flexed on the thigh, the difference in some cases being as great as 30 to 40 per cent. The author believes that the phenomenon is the result of the anatomical conditions under which the peroneal muscles functionate. Their action is always opposed by the muscles attached to the tendo Achillis, and this resistance, owing to the attachment of the gastrocnemius and plantaris to the femur is much greater when the leg is extended than when it is flexed. The observation has practical value in estimating variations in intensity of paralysis and in gauging the effect of treatment, as the power of dorsal flexion of the foot disappears last when the knee is flexed, and reappears first under the same conditions.

The Rapid Methods for the Dilatation of the Cervix from the Standpoint of the General Practitioner.—Stoeckel says that the modern tendency is to discountenance the expectant attitude that was formerly the rule in meeting certain obstetrical complications, and to resort to *accouchement forcé* under many circumstances that would

formerly have been managed in a less radical manner. Of the methods in use for accomplishing this purpose the older ones are those of dilatation of the cervix by means of the metreurynter, and Dührsen's incisions. The newer methods comprise vaginal cesarean section and dilatation with the instrument of Bossi. The cervical incisions are so apt to lead to uncontrollable hemorrhage and other complications that they would better be discarded altogether, while the operation of vaginal cesarean section, although strictly surgical and not of very great difficulty for practiced gynecologists, is still not adapted for performance by the general practitioner. The problem for the latter, therefore, resolves itself into whether he is to continue to put his trust in the dilating bag, or to adopt the new instrumental dilator. The question must still remain an open one, although the author himself inclines to the view that the sphere of utility of the Bossi instrument must remain a very restricted one. Some writers, such as Ehrlich and Heller, after considerable experience with the instrument express themselves warmly in its favor, whereas others, like v. Bardeleben, report dangerous tears and serious sequelæ from its use. The question is to form the chief subject for discussion at the approaching Congress of the Society of Gynecologists to be held at Kiel in June, and definite conclusions will probably be reached at that time.

Muenchener medizinische Wochenschrift, March 14, 1905.

The Action of Mercury.—Düring reviews various theories that have been promulgated to explain the therapeutic effect of mercury in syphilis, and says that so far at least they have led to but little definite information. The older view that the metal exerts a bactericidal or antiparasitic action is probably unfounded, for the amounts absorbed are far too small to be able to unfold a diffuse power of this sort. The most recent view is that of Schade, who, starting with the work of the synthetical chemists in the production of artificial indigo, has developed the subject of the catalytic action of the heavy metals as oxidizing agents. This action of mercury is shown by the blueing it produces in tincture of guaiac in the presence of resinified oil of turpentine, or of peroxide of hydrogen. That this action is due to electrical changes is illustrated by the change of form manifested by a globule of the metal when placed in turpentine or in tincture of guaiac. In the first fluid it becomes a flattened mass which resembles melted lead and retains any shape that may be given it, while on transfer to the tincture it at once resumes its normal characteristics. The phenomenon is ascribed to a positive electrical charge in the one fluid and a negative one in the other. Schade believes that through its catalytic stimulating effect on the tissues the mercury enables the latter to repair the damage caused by the syphilitic poison. The process is not one of antitoxin stimulation, as some authors have averred, but one of simple antagonism to the toxins.

The Effect of Fever, Infection, and Renal Injury on Suprarenin Glycosuria.—Ellinger and Seelig describe a series of experiments undertaken to throw light on the still very obscure conditions controlling the excretion of glucose by diabetics, in fever, during the course of intercurrent infections, etc. Rabbits were used as experiment animals, and the glycosuria produced by suprarenin injections was studied after the temperature had been artificially raised by injury to the corpus striatum, after cantharadin or streptococcus bouillon injections, and temporary ligation of the renal arteries. The results showed that the effect of the artificially produced fever on the sugar excretion is variable and does not as yet permit of satisfactory conclusions. Bacterial infections cause diminution of the glycosuria only when the suprarenin is injected shortly before death, perhaps owing to accompanying renal lesions. The sugar excretion is regularly reduced or caused to disappear if the renal functions are interfered with, as for example by the temporary ligation of the renal arteries. Neither these results nor those obtained on dogs having experimental pancreatic diabetes can be directly transferred to human pathology, but they indicate the importance of observations on sugar retention in diabetics with diseased kidneys, and it is to be hoped that clinicians will interest themselves in this field.

Subcutaneous Rupture of the Spleen and Its Surgical Treatment.—Neck describes a case of this injury which was successfully treated by extirpation of the spleen forty-eight hours after the accident. The patient was a boy of 16, who fell from his bicycle, striking with his left side against the edge of the curbing. He was able to get up, remount the wheel and ride to his work, but a short time afterward was obliged to seek medical aid on account of increasing pain at the site of the injury. On coming under observation he was pale, complained of pain in the left side, and the pulse was 116 to the minute, but there was no nausea or vomiting. There was evidence of free fluid in the abdomen, but it was decided to postpone operation until it should seem certain that the condition was changing for the worse. On the morning of the second day laparotomy became necessary owing to increasing pallor and cardiac weakness. The abdomen was found full of fresh and old blood clots which partially plugged a large rent in the spleen. This was quickly extirpated and the large right angled incision completely closed after careful cleansing of the peritoneum. The patient made a good recovery and has since shown no symptoms referable to deprivation of the spleen, except a low red blood count and hemoglobin value, and a relative lymphocytosis. The author calls attention to the fact that alarming symptoms did not appear until some time after the injury, an observation frequently made in such cases, and which may give rise to misleading conclusions in regard to the traumatism.

Deutsche medizinische Wochenschrift, March 2, 1905.

Mesenteric Thrombophlebitis Complicating Appendicitis.—Polya reports five cases of this fatal complication, and in discussing these, as well as others described in the literature, says that in the course of an appendicular inflammation involvement of the superior mesenteric veins may lead to thrombophlebitis. The condition is apt to be most marked in the upper jejunal veins. The obstruction and inflammation of the mesenteric veins attending appendicitis in some cases runs its course without giving rise to noteworthy anatomical or functional disturbances of the intestines, and forms part of a portal pyemia, in the other cases infarction and gangrene of the corresponding portion of the gut results, and appendicular ileus is produced. In consequence of the fairly constant localization of the lesion in the upper part of the jejunum a characteristic clinical sign of the condition is formed by muscular resistance, dulness and tenderness below the left free costal margin and in the neighborhood of the umbilicus, following subsidence of the appendicular symptoms and accompanied by evidence of pyemia. Owing to the impossibility of reaching the purulent foci in the vessels the condition is unassailable from a surgical standpoint, and the treatment must resolve itself into prophylaxis, *i.e.* early removal of the appendix when diseased.

A New Form of Blaud's Pill.—Meissner says that the intentions of Blaud in devising his famous iron pill were to have formed in the patient's stomach by a simple chemical transposition ferrous carbonate and potassium sulphate. In practice, however, in the course of the manufacture of the pills both ferrous and ferric hydrate are formed in large amounts owing to the change of a portion of the ferrous carbonate to these substances in the presence of water. The author in attempting to improve on this formula has devised the following. Exsiccated sulphate of iron 9.00; exsiccated carbonate of sodium 7.50; anhydrous cod liver oil 12.00. The mixture is filled into capsules under the precaution of excluding all bubbles of air so as to prevent any possible oxidation. The reaction taking place in the stomach forms ferrous carbonate and Glauber's salt, which is useful in relieving the constipation usually present. The cod-liver oil serves to protect the stomach from the caustic action of the ferrous sulphate before it is changed to carbonate.

The American Journal of the Medical Sciences, March, 1905.

A Review of One Thousand Operations for Gallstone Disease.—William J. Mayo and Charles H. Mayo believe that it can be fairly stated that the average mortality of operations confined to the gall-bladder is not greater than of those for appendicitis in patients of the same age and condition of health. Gallstone disease is most common in people of advanced years, often obese, and not infrequently the victim of some degenerative lesion of vital organs. In these cases of the writer's there were fifty deaths in the hospital, or an average death rate of 5%. In the benign series there were 960 cases, with 4.27%. For malignant diseases, 9 deaths in 40 operations gives a mortality of slightly in excess of 22%. In cases in which the disease was limited to the gall-bladder, including all non-perforating infections, the mortality was 2.44%; 573 cholecystostomies, mortality 2.46%; 186 cholecystectomies, mortality 4.3%. This does not include 101 cholecystostomies and 44 cholecystectomies performed as part of a common-duct operation. Of the common-duct operations, there were 137 benign, with 16 deaths, 11.7%. This, however, is really a death rate of operation and disease, and means that 7% failed to recover from the direct results of the operation, while 4% recovered from the operation, but did not gain sufficient strength to leave the hospital. Many patients were in a desperate condition to begin with. Next to malignancy and acute perforative infections of the gall-bladder and pancreas, the most serious thing that can happen in gallstone disease is involvement of the common duct of the liver. The mortality of cholecystostomy in simple gallstone disease in otherwise normal individuals was less than 1%. In 186 cholecystectomies (exclusive of 36 common-duct cases) the mortality was 4.30%, or nearly twice that of cholecystostomies. In patients who have gallstones and

who have had attacks of jaundice and other symptoms of infection of the common and liver ducts, but with no stones in the ducts, cholecystostomy is the operation of choice, as it furnishes bile drainage. The most common cause of death when the gall-bladder alone was involved was a descending infection of the common and hepatic ducts.

The Effect of Alternating Currents of Moderate Frequency on Dogs.—G. W. Crile and T. R. J. Macleod have recently made certain observations on the effect of alternating currents of high frequency on anesthetized dogs. As to the question of variability in the strength of current necessary to cause death, they are convinced that this depends upon the path through the body traversed by the current. If the heart lies in this path, fibrillary contractions will result; if not so, only vagal inhibition. Currents passing between electrodes in the mouth and rectum necessarily traverse the heart and are always fatal. With the electrodes on the head and hind limb, on the other hand, most of the current will pass along the tissue about the spinal column and will often pass by the heart. The writers call attention to a possible prophylactic measure for workers exposed to the danger of strong currents, namely, that they should wear a corset made of some conducting material, for example, copper. To be of any value, it would require to be closely applied to the skin about the shoulders and base of the neck above, and to the lower part of the trunk below, and opposite the cardiac region it would require to be separated from the skin by some non-conducting material, for example, India-rubber. It would be of no use merely to wear such a corset separated from the skin along all its length by woolens, as it is said has been practised.

The Physiological Relationship of the Proteids of the Blood Plasma.—Thomas Stotesbury Githens has performed a series of experiments on dogs. One set of animals he bled freely at intervals of several days and the blood thus drawn was used for examination. Another set of dogs he kept for two days without food and then placed them on half the quantity of meat necessary to retain nitrogen equilibrium. After several weeks of such hunger they were given unlimited quantities of meat or bread. One of the most striking facts observed is the wide variation in composition of the plasma in apparently normal dogs. The writer states that this may be due to diet or to diseases which are not sufficiently severe to show themselves; that is, mild intoxications or infections. It seems, however, that there is an attempt to retain the percentage of total nitrogen at about the same figure and this shows far less variation than do the various proteid bodies. The fact that after loss of blood the percentage of fibrinogen falls seems to show that this body is replaced with greater difficulty than any of the others, while the increase in albumin points to this as the first stage in metabolic formation of proteid. The globulins seem more irregular in behavior. The relation is also upheld by the relative decrease in albumin during hunger, as this body would not be replaced from the food as rapidly as under normal conditions. This increase in globulin, the writer continues, as well as the appearance of nucleo-albumin after loss of blood, may, however, be due to the decrease in total proteid in the plasma and the necessity of keeping it at about the same point, causing the withdrawal from the solid tissues of the body, of these proteids, in which they are especially rich. It seems certain at least that albumin and fibrinogen do not arise in the same way and under the same circumstances, and the probability of the globulins being formed from serum albumin, either in the blood or elsewhere, perhaps by ferment action, is heightened by these results.

Report of a Case of Chronic Pyelitis, Due to Bacillus Coli Communis Infection, Simulating Renal Tuberculosis.—Lewis Whitaker Allen reports this case, which came under his care. The patient was a woman of forty years. The clinical picture was as follows: A disordered stomach, accompanied by vomiting, painful and difficult micturition, a painful and enlarged right kidney, urine from the pelvis of the kidney containing large amounts of pus, and especially, and most important of all, a thin and emaciated individual, showing systemic inroads upon the vitality of the patient through a chronic period of two to three years. This picture made the diagnosis seem positively that of tuberculous infection of the kidney. At operation an enlarged and congested kidney was exposed, and was split from top to bottom into the pelvis. There were no abscesses or other evidence of tuberculous infection. A drain was pased from the pelvis through the wound and the kidney was drawn together with several sutures. Another drain was placed below the kidney, and the wound was closed. A culture from the pelvis of the kidney showed a pure culture of the colon bacillus. The urine gave the same result. After the third day irrigation was practised right through into the bladder with formalin, 1 to 2,000, and peroxide of hydrogen diluted one-third, for three and one-half weeks. Recovery was uneventful.

Scabies in the United States of America and Canada.—James Nevins Hyde says that scabies is a disease that has been known since the earliest times. The unfailing source of scabies in North America is Europe, and particularly the crowded capitals there. The conditions favoring an increased colonization of the acarus on this side of the Atlantic are well known. They are twofold and often related. The first requires an unusual increase to this country of passengers for the most part arriving in the steerage of transatlantic vessels; the second acquires an unusual increase of the crowding together of the native-born population of this country. The crowding together that comes in times of war favors the spread of scabies. The prevalence of scabies in the War of the Revolution is well known. And now scabies is developing in private practice. The symptoms are not those looked for by many physicians, but are those modified by the habits of the patients of the better classes with their more cleanly bodies and clothing. The physical welfare of the people of this country demands not only practical measures for their safeguarding, but also a national education which shall demonstrate the necessity of cleanliness.

X-Ray Treatment of Cutaneous Epithelioma.—Charles Mallory Williams declares that among the factors to be considered in estimating the value of the *x*-ray treatment of cutaneous epithelioma, the most important is the liability to recurrence. He reports a number of cases in point, emphasizing two minor factors in technique: (1) The distance between the tube and the lesion should be made as short as is consistent with the avoidance of sparking from the apparatus to the patient. In treating a large area this rule does not hold. In a small lesion, it reduces the time of exposure very materially. (2) The screen used to protect the normal parts need not be entirely opaque to the *x*-rays. The rays which affect the skin seem to have very little power of penetration. The advantages of ordinary rubber sheeting which may be folded into three layers are the ease of manipulation and the avoidance of the disagreeable tingling so often noticed when lead is used. In a series of cases which the writer reports, only one recurred. X-ray treatment is also invaluable for those patients in whom any radical operation is impossible, or inadvisable; or for those by whom it is refused. The safety, convenience, and painlessness of the method are its great advantages. Besides, if the lesions are superficial, there is a reasonable hope of permanent cure.

Suctorial and Other Insects as Plague Carriers.—Maximilian Herzog refers to many interesting observations in relation to various insects as plague carriers. He reports a case of bubonic plague which occurred in a Filipino girl. The cervical glands were the seat of the primary bubo. The writer declares that in the absence of all wounds on the head, the neck, the mucosa of the nose, the buccal cavity, and so on, and in view of the fact that plague bacilli were demonstrated in pediculi taken from the head after death, it does not seem unreasonable to assume that in this case the infection was conveyed through the bite of pediculi coming from another individual infected with plague.

Annals of Surgery, March, 1905.

A Case of Cervical Rib with Symptoms Resembling Subclavian Aneurysm.—A case is reported by J. B. Murphy, who notes that the development of a cervical rib is either from the ossific center of the transverse process of the sixth or seventh cervical vertebræ or from a separate center of ossification articulating with the body and transverse process of the cervical vertebræ in the same manner as the thoracic ribs. Cervical ribs do not develop until the patient is well into adult life. According to Gruber's classification, the rib may vary in size from a mere protuberance scarcely extending beyond the transverse process to a complete rib with a sternocostal cartilage, either individual or combined with the first rib. In about two-thirds of the cases of this anomaly the rib occurs on both sides. Symptoms are referable to pressure and displacement. Pressure may be exerted on the brachial plexus trunks, causing paresthesia and paralysis, on the subclavian artery, causing brachial ischemia, aneurysm, thrombosis, and gangrene, or there may be a tumor formation in the supraclavicular triangle. Diagnosis is made and verified by palpation and a skiagram. Immediate removal should be undertaken. The operation is not dangerous or difficult. The periosteum should be removed with the rib, in order to prevent reformation. The special case narrated is that of a man of thirty-eight years and a farmer by occupation. Symptoms commenced with disturbances of circulation in the left hand and arm and on examination a pulsating tumor was found in the left supraclavicular space. Operation was without incident, and in a few weeks the symptoms had practically disappeared.

Interstitial Hernia.—C. G. Cumston reports one case operated on with success, the patient, a girl of nine years, leaving the hospital cured in three weeks. The hernia in this case was of the inguino-interstitial variety. Generally

speaking, the diagnosis of interstitial hernia is difficult. As to differential diagnosis, we need think only of [illegible] for these growths are sometimes observed in this general region, making their exit from the aponeurosis of the external oblique muscle. The literature of the subject is gone over thoroughly by the author, who discusses the mechanical factors entering into this clinical condition. Symptomatically, interstitial hernia forms an abdominal swelling when it makes its exit through the abdominal ring, or when the interparietal sac is greatly developed and has a voluminous content. But it should be recalled to mind that there are instances of interstitial hernia where no tumefaction is present, as an example of which the inguino-properitoneal variety may be cited. The prognosis of interstitial hernia not operated on is more unfavorable than that of inguinal hernia in general, because the anatomical make up of the former renders it more liable to strangulation. The only proper procedure is a radical intervention. The longer they are allowed to go without surgery, especially if a truss is worn, the more unfavorable is the prognosis. Owing to the great variation in local conditions, no absolute rule as to method can be given and an operation may prove to be a very complicated one.

The Relation of Mechanical Distention to the Etiology of Appendicitis.—C. Van Zwalenburg notes that in a study of appendicitis four conditions point the way to etiology: (1) the constriction, (2) the concretion, (3) the bacteria always present, and (4) the distention observed in early cases. He believes that another necessary condition exists in the hydrostatic pressure in the distended appendix. Pressure upon the blood-vessels in the interior of the appendix lowers the resistance, and the germs do their work. If continued, it obliterates blood-vessels and produces necrosis and gangrene. Many attempts have been made to explain the vascular changes by trauma or pressure from concretions, foreign bodies, or kinking or torsion; but the fact that the fluid can produce pressure upon blood-vessels as well as solid bodies has been overlooked. If a constriction exists in any part of the lumen of the appendix with a concretion behind it, fluid will gradually accumulate and inflammation ensue. The fluid may at first be merely glandular secretion, and the gradual increase of pressure within the appendix cavity occludes the efferent vessels within its resisting walls. The capillaries responding to the obstruction beyond dilate and allow the escape of serum; lymphatic drainage is blocked and effusion results. This whole fluid accumulation in a cavity never sterile becomes infected, and following this infection come successively infiltration, strangulation, necrosis, and gangrene. Anything increasing tension in the colon will increase pressure in the appendix, and hence such varying causes as diarrhea, constipation, flatulency, injury, and athletic strain have been looked upon as the exciting cause of an acute attack. The author believes that closure of the appendix with consequent distention is often purely accidental. It may come on during sleep. The position of the patient may favor it. The constriction and concretion alone may exist for years without symptoms.

French and Italian Journals.

Treatment of Phlyctenular Ophthalmia by the Yeast of Beer.—Ginestous has been making investigations in the treatment of phlyctenular ophthalmia. Such happy results have been obtained in the treatment by yeast of various affections due to the staphylococci, that he conceived the idea of applying this method to phlyctenular ophthalmia. The laboratory researches have shown that the staphylococcus aureus or albus is the microorganism by far the most frequent in phlyctenulæ of the cornea. Ginestous being impressed by the uncertain results of the local application of the yeast, determined to administer it internally. It was given dry in a daily dose of four grammes, to an adult, in the form of wafers at the beginning of the two principal meals. Two grammes were given to a child. Since October, 1904, he has treated twenty-five patients by this method. In each case in which the yeast was given internally a very striking improvement took place in a short time. In certain cases the affection, which seemed rebellious to the ordinary local treatment, was cured by the addition of the yeast to the treatment. Ginestous believes that this method is of the utmost value in phlyctenular ophthalmia.—*Revue Française de Médecine et de Chirurgie, March* 20, 1905.

Uterine Fibromyoma with Vesical Troubles; Hysterectomy; Recovery.—Le Filliatre reports this case. The patient was a woman of 43 years, unmarried. For twenty years she had had painful menstruation followed by lucorrheal discharges for about ten days. Since the age of 42 the menses had been more abundant and had lasted for eight or nine days instead of for four or five. For two years the patient had felt a sensation of weight in the region of the bladder, more marked at the time of menstruation, and for eighteen months urination had been difficult. The urine often was voided drop by drop, micturition causing pain. On account of the vesical troubles, Filliatre was consulted. The general condition was satisfactory, although the patient was fat. The cervix was found to be behind the symphysis. By abdominal and vaginal palpation, a large uterine body was felt through the thick abdominal wall and was the size of a child's head. It was very irregular and the lower extremity seemed to bulge into the cul-de-sac of Douglas. On the anterior surface of the body, above the cervix, there was a tumor the size of an egg which seemed to compress the region of the vesical neck. The uterus was mobile and the adnexa seemed to be in good condition. Operation was advised. Sub-umbilical median laparotomy was performed. When the peritoneum was incised, the uterus was seen to be large, fibromatous, very irregular, and mobile. There were no adhesions to the bladder and the adnexa were normal. Supravaginal hysterectomy was performed. Drainage of the small pelvis was instituted. The drain was removed on the fifth day. Recovery was uneventful, and the previous symptoms entirely disappeared.—*Bulletins et Mémoires de la Société Anatomique de Paris,* January, 1905.

Vegetative Endocarditis in the Course of Typhoid Fever.—Roque and Corneloup had this interesting case under observation. The patient, a woman of 26 years, had never before been ill. She was in her third week of typhoid fever before she entered the hospital and before the diagnosis was made. The pulse was 150, but the heart was not large. The apex was in the fifth space; the first sound was not clear and there was a slight souffle. The tachycardia persisted. Arhythmia was constant. A variable systolic murmur was present, loudest at the apex. Towards the end, thoracis edema developed. The patient had entered the hospital on November 10, and she died on December 21. Autopsy revealed extensive vegetations on the edge of the mitral valve, forming a crown over the whole border. Otherwise the valves were supple and not thickened. It was a vegetative endocarditis exclusively marginal. Although the cardiac muscle, examined macroscopically, did not appear abnormal, fragmentation was seen microscopically and a hyaline condition with increase of volume resembling the degeneration of Zenker. There were, besides, round cells in increased numbers in the interstitial spaces. From the results of bacteriological examination, these investigators are unable to affirm absolutely either the presence or absence of the bacilli of Eberth in the vegetations.—*Lyon Médical,* March 18, 1905.

Treatment of Hemorrhages of the Intestines.—Mathieu and Passier have had excellent results in the treatment of intestinal hemorrhages of typhoid fever by hot water and calcium chloride administered by irrigation. The amount of calcium chloride in twenty-four hours which is given to a patient is one gramme by mouth and three grammes by irrigation. These workers have found that the calcium chloride is habitually well tolerated. The duration of treatment varies according to the dose. Four days is considered long enough by certain authorities. Others continue it for a longer time when the doses are very small. The elimination of the salt is sufficiently rapid so that it does not accumulate in the organism. It is well always to find out first if the patient has normal kidneys before giving it. It is considered beneficial to clear the intestine of extravasated blood. Putrefaction can then not take place, and one cause of intoxication is removed. The irrigations should be given carefully and slowly. About a liter of water is used; the patient should be in dorsal decubitus, and the operation should take about fifteen minutes.—*Revue Française de Médecine et de Chirurgie,* March 20, 1905.

Ozonotherapy and Hematolysis in Pertussis.—A. Muggia and M. Bertolotti have used ozone in thirty-five cases of convulsive cough, with encouraging results. Ozone acts in pertussis as a powerful antispasmodic, with almost specific effect, especially in the more severe cases. After ten to twenty sittings, one each day, the most rebellious attacks are cut short. This action is antispasmodic rather than antitoxic or antimicrobic, as is shown by the examination of the blood formula, which was made in every case. There is a hyperleucocytosis in pertussis, but there is a predominance of the large mononucleated elements, with oval nucleus and not staining well. Hence there is no lymphocytosis. There is a true inversion of the leucocyte formula in the blood, in the sense that the polynucleated elements and lymphocytes are diminished, and the large mononucleated elements are increased. This inversion corresponds to a reaction of the system against the toxic virus. Pertussis is an infective disease that leaves the patient with a more or less permanent immunity, and this immunity depends on the increase of the mononucleated leucocytes. Ozone in no way modifies the blood formula; therefore it has an antispasmodic, not an antimicrobic action. It is also a good stimulant of the hematopoietic organs, and there is an increase of red blood corpuscles and of hemoglobin. The ozone used was generated by electricity.—*Rivista di Clinica Pediatrica,* February, 1905.

Book Reviews.

Die Wirkungen von Arzneimitteln und Giften auf das Auge. Handbuch für die gesammte ärztliche Praxis. Von Dr. L. Lewin, Professor in Berlin, und Dr. H. Guillery, Oberstabsarzt in Coln. II. Band [illegible] figuren. Berlin: Verlag von August Hirschwald, 1905.

The second volume of the work by Lewin and Guillery is one of 1,046 pages. The sixth division of the work (five divisions are included in Volume I) is devoted to a consideration of the influence of fungi on the eye. The various fungi are considered under three groups: (1) Those which produce local lesions; (2) those which produce local lesions and are also capable of producing general systemic disease; (3) those which affect the eye and its appendages secondarily to a general systemic infection. This part occupies 750 pages. It treats exhaustively of all the varieties of fungi known to be pathogenic to the eye, gives abstracts of recorded cases, and includes a large bibliography. This part of the work is really a complete treatise of the bacteriology of the eye, and is very valuable.

Part 7, which completes the text of the volume, takes up the subject of the toxic effect of various substances on the eye, as well as the escharotic effect of various drugs and chemicals. A comprehensive description of each substance, its effect on the eye, and the appropriate treatment are given. This division is subdivided to classify properly the different varieties of substances that are included in this category. A list of the names of writers whose articles were consulted follows, and the volume is completed by a comprehensive index.

The work is by far the most complete of its kind. It should be available to all ophthalmologists.

Massage des Membres. Par le Dr. Dagron, ancien interne des hôpitaux, ancien aide d'anatomie à la Faculté, avec 101 figures dans le texte. Paris: G. Steinheil, 1905.

This book commences with a brief historical sketch of massage, which is succeeded by a somewhat lengthy chapter on the general technique of massotherapy. This chapter is important, and gives much necessary information; it emphasizes the necessity for simplicity in the various movements required, and also shows that the human hand is not only the best, but also the only instrument needed. The different regions of the body (limbs and joints only) are then successively dealt with, and an outline of the necessary anatomy and physiology of the part is given; this is followed by a clear description of the methods of massage as indicated in various injuries and diseases. The ground is well covered, and the book will, we doubt not, do much to place massage in its rightful position as a therapeutic agent.

The Differential Diagnosis of Syphilitic and Non-Syphilitic Affections of the Skin, Including Tropical Diseases. By George Pernet, Assistant to the Skin Department, University College Hospital, London; late Pathologist to the Hospital for Diseases of the Skin, Blackfriars. London: Adlord & Son, 1904.

This little volume commends itself at once by the great importance of a subject too much neglected by students and practitioners; by the easy style of what the author calls a "survey" of the subject; by the information included relating to tropical and rare affections, and by the light weight which enables one to hold it with one hand.

Strangely enough, the term "chancroid" does not appear, though chancrelle and German synonyms are given for the soft sore. Like most British authors, he speaks of epithelioma and rodent ulcer as though they were distinct affections.

While in no sense exhaustive, its reading through will repay even the well informed, and the student who has seen enough patients to get an idea of appearances will benefit by its study. There are no illustrations.

International Clinics. Edited by A. O. J. Kelly, A.M., M.D., Philadelphia. Vol. IV. Fourteenth Series. Philadelphia and London: J. B. Lippincott Company, 1905.

This quarterly of illustrated clinical lectures and specially edited departments, having the cooperation of Osler, Musser, Rotch, Walsh, Harold, and other home and foreign talent, maintains its place in the sphere of periodical literature and review.

Some of the articles treat of medicinal intoxication (Hayem), dechloridation treatment (Javal), radium (Metzenbaum), the desperately ill (Lejars), polycythæmia (Weber and Watson), the importance of pathological diagnosis (Solis-Cohen), the incidence of gout (Duckworth), albumosuria (Senator), general enlargement of the liver (Crombie), functional heart murmurs (Rudolf), Glenard's disease (Gallant), etc.

The general scope and tone of the work are high and the articles in the main interesting and instructive, with a fair amount of new matter.

Röntgenologisches Hilfsbuch. Gesammelte Aufsätze von Ingenieur Friedrich Dessauer. Band I. Würzburg: A. Stuber's Verlag, 1905.

This is a collection of writings upon the principles and most important curative methods of Röntgen procedure. In several chapters various technical questions are considered and interrupters, spark length, apparatus, [illegible] diagraphy, and radioactivity form separate chapters.

There are thirty-three illustrations. If this is to be regarded as a sample of other volumes, the whole will be a decided addition to the literature of radiology.

Electro-Static Modes of Application, Therapeutics, and the Uses of the Röntgen Ray. By William Benham Snow, M.D., Professor of Electro-Therapeutics and Radiotherapy in the New York School of Physical Therapeutics, Editor of the *Journal of Advanced Therapeutics*, and late Instructor in Electro-Therapeutics in the New York Post-Graduate School, etc. Third edition, revised and enlarged. With over one hundred illustrations, including ten full-page half-tones. New York: A. L. Chatterton & Co., 1905.

There have been scarcely any changes made in this edition and no new chapters added. In this respect the work does not come up to the requirements of the day since views upon the possibilities of the *x*-ray and its limitations may be said to have undergone some change, and new observations are of almost daily occurrence. The dangers to the operator from effect upon important organs apply equally to the patient of either sex and these questions are claiming much attention just now. Some illustrations have given way to new ones, but in a future edition this might be carried still further.

The author is to be congratulated on the necessity for a new edition so soon after the second.

Les Indications des Interventions Chirurgicales dans les Maladies Internes, à l'usage des Médecins Praticiens, par le Professeur Hermann Schlesinger (de Vienne) traduction française de MM. les Docteurs Lichtwitz et Sabrazès, Professeur agrégé, Médecin des Hôpitaux de Bordeaux. Première partie: Maladies du système nerveux, des os et des articulations, de la plèvre, du médiastin, du système circulatoire et du tube digestif. Paris: Vigot Frères, 1905.

This is a French translation of the first part of a book already well and favorably known to German physicians (two of the three volumes having already appeared in Vienna), but of which we know of no counterpart in English literature. The work is of a thoroughly practical character, and may be described as a work on surgery for physicians or internists. It not only fulfils the promise of its title, as setting forth the indications for operation in internal disease, but also discusses the queston of diagnosis based upon the essential symptoms in the special cases. Guided by a book of this nature, the medical man will be in position to recognize the limits of his more gentle art and to summon to his aid betimes the man of action, the miner and the sapper of therapeutic warfare.

The Life of Florence Nightingale. By Sarah A. Tooley, author of "Personal Life of Queen Victoria," "Life of Queen Alexandria," "Royal Palaces and Their Memories," etc., etc. With twenty-two illustrations. New York: The Macmillan Company; London: S. H. Bousfield & Co., Ltd., 1905.

On October 21, 1854, the heroine of this true tale, more interesting than many a work of fiction, left London with a band of thirty-eight nurses for service in the Crimean War, and the author tells us that the writing of the Life was undertaken with the object of marking the semicentenary of this epoch-making journey. It is a matter of congratulation that this mother of nurses was still alive to celebrate her jubilee last autumn. A pleasing fact, which bears witness to the veneration with which the rising generation in England regards this prototype of the Red Cross angel, is related by the author in her preface to the Life. A short time ago the editor of *The Girl's Realm* took the votes of his readers as to the most popular heroine of modern history. There were fourteen names submitted for the suffrages of the young readers of this magazine, and of upwards of 300,000 votes cast, 120,776 were for Florence Nightingale.

The biography is most interesting in all its parts—the childhood and early life, in which the first signs of a bent toward nursing were manifested; the young womanhood in which the nursing sisterhoods in Germany and France were visited and the future work of devotion to the sick and wounded in the Crimea, though as yet undreamed of, was being prepared for; the mature years in which the great work was achieved; the later years of semi-invalidism, in which the training schools at St. Thomas's Hospital and elsewhere were established and the work of district nursing was advanced; and the closing years of bodily inactivity upon the bed, but of mind still alert and busied with thoughts of helping the poor and the sick.

Society Reports.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, March 13, 1905.

THE PRESIDENT, DR. THOMAS E. SATTERTHWAITE, IN THE CHAIR.

The Constitutional Treatment of Bright's Disease.—Dr. WILLIAM H. PORTER said that scientific therapeutics in renal diseases called for a method of treatment that had for its aim not alone the removal of symptoms, but the elimination of all the etiological factors entering into the production of the pathological lesions. It should also aim to remove the pathological lesions, and bring about as nearly as possible a normal state in the organs implicated. The etiological factors were comparatively simple in connection with the parenchymatous group, but were much more complex in dealing with the diffuse form of renal lesions. For the parenchymatous group they might briefly be stated as eating and drinking too much, putrefactive fermentative changes in the alimentary tract and the indirect or direct action of microorganisms, acting either in the intestinal tract or within the system. For the diffuse group we had all the above factors, to which were added a more or less rapid disintegration of the epithelial cells, the passage of toxic matter through the kidney, either paralyzing the nerve endings in the kidney or acting reflexly from this point, and thus interfering with the circulation through the kidney.

The treatment of renal lesions was best considered under two common headings; first, that of prevention, and, second, that which was applicable after positive development of the renal lesion. Knowing that the parenchymatous lesions, or those involving the epithelial structures alone, were largely due to overeating and drinking, but especially the former, great care should be exercised in the regulation of the diet. Knowing also that putrefactive changes in the proteids in their passage through the alimentary canal were frequently responsible for this class of kidney lesions, this tendency to putrefactive fermentation should be carefully corrected. The damaging effects of the bacteria, acting either directly or indirectly, should not be neglected in the preventive treatment. In health, as well as in disease, the quantity as well as the quality of the food taken should always be kept well within the oxygenating capacity of the animal economy, if overwork and a faulty nutrition of the renal glands was to be avoided.

What had been said in regard to the prevention of the epithelial and interstitial changes singly in the kidney, applied with equal force to the prevention of the combination of the two when developed together, as occurred in that set of lesions known by the name of a diffuse lesion of the renal structures. The predominance of the one or the other type of lesion, or the combination of the two in the same kidney, was governed by the kind and amount of the toxic products that were brought to bear upon the renal cells or upon the nervous mechanism that controlled the circulatory and nutritive functions of the renal glands. Therefore, it became clearly apparent that all forms of renal lesions were dependent primarily, and in a very large measure, upon what the individual ate and drank. Aside from this, lack of exercise in the open air, sedentary habits, unhygienic surroundings, overwork, both mental and physical, especially the former, should never be lost sight of as factors that entered into the possibilities of a perfect or imperfect digestion, circulation, and utilization of the food products taken into the system.

When it came to the treatment of the actually existing renal lesions, as evidenced by the profound changes in the oxidation products found in the excreta, particularly in the urine, and which reached their height in the form of albumin, sugar, casts, etc., a still more arduous undertaking confronted the therapeutist. All that had been said in reference to the prevention of these lesions applied with even greater force to the more difficult task of removing the damage already done to the renal structures, and bringing them to such a nutritive condition that they could again perform their function normally. In treating the fully acquired lesions, out-of-door exercise must be insisted upon with as much precision as the use of medicines. Exercise should not be taken to the extent of producing exhaustion, but in sufficient amounts to increase the oxygenating capacity of the system, so that it would be enabled more perfectly to oxidize the proteid constituents. The clothing should be such that it would prevent undue chilling of the surface of the body from the sudden changes in the atmospheric temperature. In fact, the best results were obtained where the surface of the body was kept in a gentle perspiration at all times. The chief and all-important treatment, however, consisted in the perfect management of the diet in accord with our advanced knowledge as to its composition and utilization by the system. Here, as in all other diseased conditions, as well as in health, the well-regulated mixed diet was the ideal one. The milk diet, which had been so long extolled in the dietetic management of all renal affections, was largely deficient in that complex substance in which the iron and phosphorus atom was combined with a proteid, known as nucleo-albumin, and out of which the hemaglobin for the blood and the lecithin for the nerve tissue was formed by oxidation reduction. Hence, milk could not be considered an ideal diet in any class of lesions in which a progressive anemia was one of the essential features, as was the case in connection with all renal lesions.

A well-regulated mixed diet was one that was composed of both the vegetable and animal class, but in which the latter largely predominated. When nature, unaided, could not digest such a diet, she often could be assisted by the judicious administration of medicinal agents. Careful experimentation upon the human subject had conclusively demonstrated that the proteid of beefsteak or red meat was the most easily digested, assimilated and oxidized of all the proteids, the loss being only two per cent. Eggs ranked next, and milk came third on the list, and so on down through the list of food products until oatmeal was reached, which was the most indigestible of all known substances, for with oatmeal there was a loss of eighty per cent., as compared with the amount ingested.

Medication in renal diseases, as formerly used, and as it was still employed in many instances at the present time, simply added fuel to the fire, and absolutely prevented nature from accomplishing what she might otherwise do, and thus prevented recovery. On the other hand, when the exact chemical laws were fully comprehended and so-called medication applied in full accord with those phenomena and principles, nature was greatly aided in her efforts, not only to prevent the development, but in bringing about a physiological cure of these diseases. The treatment should be directed not so much to the kidneys as toward removing the etiological factors that entered into the production of those lesions. Operative interference did not remove any of the etiological factors, unless it was the loss of contractility and expansibility of the renal gland, taken as a whole.

Dr. REYNOLD WEBB WILCOX said he agreed with Dr. Porter that the difference between an animal and vegetable diet was rather a difference of terms than of kind: as the speaker had pointed out, the vegetable proteids were more difficult of oxidation than the animal. He also gave his hearty assent to the statement that what was properly known as chronic interstitial nephritis was the result of a condition that was not limited to the kidneys, and was, more correctly speaking, a disease of the arteries, the arterial changes being present in every organ and tissue of the body; therefore neither decortication nor pelvic irrigation had any influence upon the course of the disease.

The drug treatment of renal disease, Dr. Wilcox said, had probably, at one time or another, embraced every known drug in the Pharmacopœia. Among the more recent advances in the treatment of chronic parenchymatous nephritis, the speaker mentioned dechloridation; also the

limitation of the quantity of fluid ingested, and the more careful regulation of the food. The daily output of sodium chloride in the urine should be kept track of, and the daily weight of the patient would furnish the therapeutic indication as to what amount of sodium chloride it would be necessary to eliminate from the food, and would also give a pretty accurate idea of when to expect the occurrence of dropsy. The diminution of the amount of fluids ingested would oftentimes be followed by an increased flow of urine. By a "water-free" diet was meant one that did not allow over a liter and a half of water, exclusive of that taken in the food. But occasional days of free water drinking should be allowed.

The so-called diuretics, Dr. Wilcox said, should be avoided in the treatment of chronic renal disease. In the chronic interstitial form of nephritis, the sphygmograph was of great value as an aid in the early recognition of the disease. The only drug he mentioned was erythrol tetranitrate, which in doses of one-half to one grain was efficacious as a vasodilator: in its action it resembled nitroglycerin and amyl nitrite, but it differed from them in being less powerful, but more prolonged. For the persistent headaches of chronic interstitial nephritis, and for the purpose of relieving coma and convulsions, tapping of the spinal canal had been practiced with much success. The effects of this procedure were purely mechanical, relieving pressure. High intestinal irrigations, as carried out by many, and as studied experimentally and physiologically by Kemp, were very beneficial in the treatment of this class of cases. By this method, toxic substances were eliminated, the flow of urine increased, and the heart strengthened. The speaker said he had seen patients who were apparently in a comatose condition restored to a state of comparative usefulness by this method of treatment. Under proper dietetic, hygienic, and medicinal treatment the majority of patients suffering from renal disease were curable; of those not curable, more were capable of enjoying fairly good health for many years.

The Treatment of Bright's Disease by Lavage of the Renal Pelves.—Dr. Winfield Ayres presented this paper, and offered the following conclusions: 1. Not enough importance had been given to the probability that a large percentage of cases of chronic nephritis in which no discoverable cause for the inflammation could be found were really due to an extension of the inflammation from the renal pelvis. 2. Lavage of the renal pelves was only applicable in selected cases of nephritis. 3. Lavage of the renal pelves would certainly cure a beginning nephritis that was due to extension of inflammation from the renal pelves. 4. Lavage of the renal pelves in sub-acute and chronic parenchymatous nephritis would check the disease and markedly improve the general condition of the patient in those cases that had not reached the stage known as cirrhotic kidney. 5. Lavage of the renal pelves for nephritis by one who was not properly trained in the technique could not possibly improve the condition of the kidneys, and would do harm.

The Treatment of Pyelitis.—Dr. Howard A. Kelly of Baltimore, Md., read this paper. (See page 521.)

Dr. F. M. Johnson of Boston, Mass., said the papers of the evening, embracing as they did the treatment of renal disease from different standpoints, opened a wide field for discussion. In the great majority of the cases of Bright's disease that he had treated by lavage of the renal pelves during the past year, various methods of diet had been tried and had failed, but the patients seemed to improve when, in addition to the restricted diet, lavage of the pelves was done. In experienced hands, the speaker said he did not regard lavage of the kidney pelvis any more serious a procedure than he did lavage of the bladder.

Dr. George M. Edebohls said the work done by Dr. Kelly in this particular field was of such an ultra-progressive kind that it stood in a class by itself, and he knew of no one who was competent to discuss it excepting Dr. Kelly himself. He had been much interested in Dr. Ayres' very radical contribution to the treatment of [illegible] by lavage of the renal pelves, and while the [illegible] made by the author in his conclusions were unassailable, they were not borne out by the report of the cases upon which they were apparently based. From the data contained in Dr. Ayres' paper, exception might be taken to the diagnosis of even the so-called incipient cases of Bright's disease. It was a matter of every-day observation that a trace of albumin, and a few hyalin and granular casts were present in probably nine out of ten cases of movable kidney, but the speaker said he had never regarded these findings as an indication of chronic nephritis or of incipient chronic nephritis. When the kidneys were anchored these abnormal constituents of the urine disappeared, but this did not indicate that the patients were cured of incipient chronic nephritis, but simply that the congestion of the kidney had been relieved. It would take many years of careful observation, the speaker said, before even an approximate idea could be formed of the value of lavage of the renal pelves in the treatment of Bright's disease.

Dr. Edebohls said he could recall cases in which a pain like that described by Dr. Kelly was entirely relieved by fixing a movable kidney, after extirpation of the tubes and the appendix and even sometimes the uterus itself had failed to affect it. It might be that in those cases the abnormal position of the kidney had given rise to a slight hydronephrosis or pyelonephrosis, which was relieved by fixing the organ in its proper place. It was not advisable, the speaker thought, to immediately resort to ureteral catheterization in dealing with these cases. While the introduction of a catheter into the ureter was a comparatively harmless procedure in the hands of Drs. Kelly and Ayres, there were probably fewer men to-day who could be safely trusted to do it than there were men who were competent to do a major operation on the kidneys.

Dr. Willy Meyer said that Dr. Kelly had shown in his instructive paper that in the majority of cases of pyelitis the cause was a mechanical one, namely, a stone in the pelvis or ureter, or a stricture of the ureter. Other causes that might be mentioned were stricture of the urethra in the male, cases of ascending infection without the presence of stone or stricture, and those due to infection through the blood or lymphatic current. Cases that were the result obstruction of the ureter by stone, or by pressure from without—and these were especially frequent during pregnancy—were amenable to treatment as soon as the cause of the trouble was made out. The same was true of those following prostatic enlargement. In those cases, no matter what operation was done for the removal of the enlarged prostate, the pyelitis would disappear if proper drainage was established. It was not always an easy matter to recognize a pyelitis, as the method of ureteral catheterization practiced by Dr. Kelly in females was a much more difficult matter in males.

Dr. Meyer said that an ordinary, uncomplicated pyelitis following typhoid fever or other infectious disease would often be cured by itself. In adopting the therapeutic procedure described by Dr. Ayres, it was important to differentiate between pyelitis and Bright's disease. If the former condition was recognized at an early stage, and treated by lavage of the pelvis of the kidney, we might be able to effect a cure and prevent the development of pyelonephrosis. How it was possible, however, to benefit a patient with chronic parenchymatous inflammation of the kidneys by washing out the renal pelves was a conundrum which the future might explain. While the bloodless procedure of ureteral catheterization had its place in dealing with septic conditions of the kidney, it should not be used to the exclusion of more radical surgical measures in properly selected cases.

Dr. Frederic Bierhoff said all would agree that attempts to catheterize the ureters or wash out the renal pelves in the course of acute Bright's disease would be unjustifiable, and in order to be entitled to serious consideration in the treatment of chronic renal disease, the procedure must

either be based upon a correct appreciation of the histological and pathological condition it aimed to correct, or else it must show indisputable results. According to the statements set forth in Dr. Ayres' paper, neither of these conditions were fulfilled. Lavage of the renal pelvis was simply a further development of ureteral catheterization: both were serious operations and should be resorted to only in cases of imperative necessity, and then only by men who were dexterous in these manipulations, and under the most stringent antiseptic precautions. The fluid injected through the ureteral catheter could penetrate no further than the calices, and whether plain or medicated, its action must of necessity be confined to the mucous membrane with which it came in contact. Admitting this, Dr. Bierhoff said he was unable to see how such applications could have any effect whatever upon a process which all authorities conceded had its origin in the remoter tissues of the kidney. In chronic Bright's disease the tissues of the kidney were affected from the beginning, the exciting cause being carried by the blood current, and the speaker said he failed to see how any fluid applied to the pelvis or calices of the organ could have the slightest effect upon the tissues of the Malpighian tufts. The mere reduction in the quantity of albumin in the urine was of no great importance. That could be effected by rest in bed, by various forms of diet, and by methods of treatment outlined by Dr. Porter. The same thing applied to dropsy and the presence of casts in the urine. Their disappearance did not signify that the kidney lesion had been cured. From the facts thus far set forth, Dr. Ayres was not justified in making any claims whatever in regard to the method of treatment proposed.

Dr. Boleslaw Lapowski said he thought the method of treatment described by Dr. Ayres was based on an erroneous idea, as he acted on the theory that by washing out the renal pelves he prevented infection of the kidneys from the pelves. This conception as to the method of kidney infection was not based on facts. Taking, for example, a gonorrheal infection of the kidney, Dr. Lapowski said there was not a single case on record in medical literature in which the gonoccocci entered the kidney through the pelvis, while there were many cases which proved that the gonococci passed from the circulation through the kidney into the pelvis. When the gonococci had once found a lodgment in the mucous membrane of the pelvis, no amount of lavage—in fact, nothing short of the use of the curette—could remove them. For that reason, the treatment of a pyelitis of gonorrheal origin by lavage was useless.

Dr. Albert A. Berg said that the term chronic Bright's disease was not synonymous with chronic nephritis. We had reached that stage in our knowledge of the pathology and histology of kidney diseases where we should relegate to the past the former term, and study the various lesions under the name of chronic nephritis. They were due to many causes, among them the tubercle bacilli, floating kidney, stone in the kidney, various toxins resulting from the acute infectious diseases, chronic suppuration, and so on. In a case of chronic nephritis due, for example, to prolonged suppuration, the speaker thought it would take a good deal of lavage of the renal pelves to restore such a kidney. The same was true of other forms of chronic nephritis, but under certain conditions the procedure might be of value. In dealing with an ascending infection from the bladder, associated with obstruction to the free drainage of the pelvis of the kidney, such an organ might be greatly benefited by ureteral catheterization and lavage, but to advance the procedure as a panacea for all forms of chronic nephritis was not justifiable without more convincing proof.

Dr. Ayres, in closing, said the method of treatment he had described was applicable only in selected cases of nephritis. He thought it would cure a beginning nephritis that was due to extension of the inflammation from the renal pelves, but he had not claimed that it would cure advanced cases. The speaker said he had used the ordinary straight-tube cystoscope in the male ureter, and with the waxed tip had located ureteral stones. It had not been his purpose to draw any absolute conclusions regarding this method of treatment, as further experience was essential before that could be done. In reply to Dr. Lapowski, the speaker said he had never found any gonoccocci in the urine from the kidney pelvis.

Dr. Kelly, in closing, emphasized the importance of more frequent autopsies, so that the objective conditions to be met with in these cases could be better studied.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated meeting, Held March 3, 1905.

The President, Samuel Lloyd, M.D., in the Chair.

Undeveloped Wisdom Tooth Simulating Sarcoma.—Dr. Alfred S. Taylor presented a young man who, seven years before, had been injured while boxing. A sinus developed over the ramus of the superior maxilla. It was probed and treated in every possible manner without success. At length Dr. Taylor operated and removed a granular, pulpy mass, which appeared to be a sarcoma of the jaw. It proved, however, to be a metamorphosed unerupted wisdom tooth. The speaker had been able to find but twenty cases recorded in the literature of the subject.

Suppurative Tuberculosis of the Elbow; Resection and Iodoform Wax Filling.—Dr. Charles A. Elsberg presented this case. The patient was a girl about 14 years of age, whose elbow joint had been resected and scraped, and indeed subjected to almost every form of surgical intervention for the treatment of chronic osteomyelitis. The last time that operation was undertaken a thorough curettage had been done; the parts had been dried and an iodoform wax filling had been carefully packed into the cavity. A portion of this wax was extruded within two weeks, but the pain and the discharge ceased. The patient wore a light brace capable of flexion and extension only. The object of the brace was to wear upon the surface of the bone, which was being laid down as the wax was absorbed, facets which should simulate those of the normal joint. As in the many other cases which he had operated upon, the speaker had noted here the tremendous stimulation of the bone tissue afforded by the iodoform wax filling. Whereas for the past five years the arm had been entirely helpless, the child was now able to flex and extend the forearm to a very encouraging degree.

Perforating Bullet Wound of the Chest and Abdomen.—Dr. Elsberg also presented a woman, 33 years of age, who was struck by a 32-calibre lead bullet, which came from an unknown source. It had entered just above the right nipple and had passed downward, inward and to the left. She experienced some shock at the time, and four days later became profoundly septic. Dr. Elsberg immediately explored the region of the wound, made an incision near the xiphoid over the course of the bullet, and then performed laparotomy, discovering a perforating wound of the liver, of both walls of the stomach, and of the left kidney. This latter organ was removed because it was very badly injured. The woman improved, but as time went on developed a septic temperature and gradually passed into a most frightful condition. Incisions and aspirations were made all over her entire abdomen and trunk as suggested by various consultants in the hope of finding the pus, but all to no purpose. Finally in despair of saving her life and at a time when she was almost moribund, Dr. Elsberg did a transpleural hepatotomy and succeeded in evacuating a large abscess cavity. From that time on, her progress toward recovery was uneventful.

Acute Intussusception in an Infant.—Dr. Edward W. Peterson presented a child four months and ten days old, who had never previously been sick. Suddenly, without warning, what the attending physician called bloody dysentery developed. The infant at this time had all the characteristic signs of intestinal obstruction and shock.

On operation, it was found impossible to reduce the invagination successfully. Four inches of the ileum, the cecum, and an inch of the ascending colon were resected. On the fourth day the child suffered great pain. This was found to be due to the fact that the button was lodged in the rectum. The patient was discharged on the fifteenth day.

Exstrophy of the Bladder.—Dr. RAMON GUITERAS presented this patient, a strong and healthy man with an exstrophy about four inches in diameter. The pubic bones separated at the symphysis from three to four inches with the result that the only part of the penis to be seen was simply a glans attached to the prostatic portion without any apparent penile portion. The ejaculatory as well as the prostatic ducts could be seen. There were twenty-four or twenty-five openings of prostatic ducts, which extended up into the prostatic follicles beside the ejaculatory ducts. The patient has suffered since childhood and had tried a great variety of urinals without relief. At all times there was a leakage of urine causing chafing. At last he gave up trying to use a urinal and was continually wet. His bladder was much inflamed and mucus and ulcers could be seen on the walls. His occupation, that of blacksmith, kept his body flexed so that the clothes were kept away from the raw surfaces. When the question of an operation was discussed the choice was either of a plastic operation, taking a flap from around the bladder, or a transplantation into the rectum. It was thought that the plastic operation would give better results. The transplantation of the ureters into the rectum caused at times an irritable condition of the rectum. The urine escaping from the rectum would produce an irritation about the anus and the cleft between the nates and perineum. Again the rectum might become inflamed. This inflammation might extend to the ureters and even to the kidneys producing a pyelitis, and a pyelonephritis was usually fatal. Dr. Guiteras used a modification of Wood's operation, making a skin flap, measured so as to cover the walls of the bladder. In this patient the skin of the abdomen seemed to be devoid of hair, but if hair had been present, electrolysis would have had to be done first. The flap was brought down over the bladder, freeing the edges of the skin about its circumference and the bladder, bevelling both edges. He sewed the skin flap to the base of the bladder; then he took two inguinal flaps and brought them over the raw surfaces. These flaps came in contact with the raw surfaces of the abdominal flap. Catheters were introduced into the ureters and brought out through the canal made by the plastic operation. A soft rubber catheter was introduced into the bladder through the urethra. The patient made an uneventful recovery. In many of these cases a number of plastic operations are required, but in this case there were but two sinuses; one healed about three days after operation and the other in less than three weeks. The denuded area was covered by skin grafts taken from the thighs. He attributed the fact that the artificial bladder was able to hold water to the catheters that had been introduced into the ureters in this way, carrying the urine directly to the outside. After two days the ureteral catheters would not drain and the soft rubber catheter was left in the bladder. He believed this was the secret of the rapid healing of the wounds in this case. The patient was up and about and could hold two ounces of urine while standing and more when reclining. If the patient lived a catheter life the result would be almost as good as though he had but slight control of the bladder. His prostate was about one-half an inch up from the anus. Before the operation one could palpate the prostate because of the absence of the pubes. Six weeks after the operation the patient experienced his first erection, which showed a beginning activity of the genital apparatus. If the pelvis had been strapped and pressure applied when the patient was born the pubic bones might have become approximated.

Dr. HOWARD LILIENTHAL considered this to be the best result he had ever seen and ascribed the remarkable success of the operation to the retention of the ureteral catheters.

Deformity Following Dislocation of the Hip.—Dr. RAMON GUITERAS exhibited a radiogram which showed extensive destructive processes to have acted upon the acetabulum and the head of the femur on both sides. The case was that of a child of Russian Hebrew parentage about five years of age. The lesion was undoubtedly of tuberculous origin, but the two peculiar things about it were, first, that the child showed no evidence of pain, although flexion was very marked and, second, that it was bilateral.

Exophthalmic Goitre Treated with Antithyroidin.—Dr. WILLY MEYER said that Möbius had been the first to endeavor to treat this affection with antibodies. Lanz had prepared a serum from dethyroidized goats, and had obtained some remarkable success with the method. Dr. Meyer exhibited a man about forty years of age in whom he had made use of a glycerinated preparation. It had been given both internally and hypodermically. In six months the patient had lost his tremor and had a pulse of 96 and was able to return to work. No relief of the exophthalmos had been obtained.

Dr. JOHN ROGERS said that he was sorry to pour any cold water on so promising a report, but he felt constrained to say that for two years he had been watching Möbius' work very closely and had made a particular study of these cases during the past five years. The conclusion which had been forced upon him was that they improved, but that such improvement was only temporary.

Dr. JOHN ERDMANN also reported a case which he had treated by this method and which had failed to improve.

Gastroenterostomy by Means of the Elastic Ligature.—Dr. WILLY MEYER showed this patient and also exhibited a new type of ligature which he had found extremely satisfactory.

Posterior Gastroenterostomy by Maury's Twine Triangular Stitch.—Dr. JOHN A. BODINE presented a middle-aged German woman who showed a healthy scar following laparotomy. She was well nourished and described herself as being in perfect health.

The Twine Triangular Stitch for Gastroenterostomy and Enterostomy.—Dr. J. W. DRAPER MAURY read this paper. The speaker stated that the work represented the collaboration of a number of studies made by undergraduate students of the medical department of Columbia University in the Surgical Research Laboratory. He said that the object of the paper was to present in full detail the method of application of the twine triangular ligature and to report the experimental and clinical status of the method. A series of drawings representing the different steps of the technique were then thrown upon the screen, and the method of its execution was analysed. The speaker said that the assertion that the technique was easy of execution must be grounded upon fact, because the students had had no difficulty whatsoever in learning to insert the triangular stitch. He said that the stitch consisted simply of two isosceles or equilateral triangles superimposed. The apex of one lay in the stomach and its base in the gut, while the apex of the other lay in the intestine and its base in the stomach. The object of the stitch was to combine the advantages of the McGraw technique and of the Murphy button and to do away with the well-known objections to each of these classical methods. The objections to the button were its well-known faculty of being retained in the gut, of falling into the stomach, or of perforating the alimentary canal almost anywhere in its course and causing death from peritonitis. Its chief advantage lay in the fact that it punched out an opening. The disadvantage of the McGraw method consisted in its failure to punch out the juxtaposed walls of the viscera, a simple slit only being made. Its advantage consisted in the speed of its application and particularly in the fact that there was very little danger of contamination at the

time of its introduction. In this respect, it was universally conceded to be superior to the Murphy button and, of course, to the open method of anastomosis. The twine triangular stitch had been demonstrated to punch out with a certainty equal to that of the Murphy button and it had been shown to be just as advantageous as the McGraw ligature in avoiding peritonitis from a soiling of the peritoneal cavity. The technique given was as follows: A posterior row of Lembert stitches should first be inserted. A piece of twine strong enough to be unbreakable by the hands and threaded on a round needle about 8 centimeters in length should be inserted at the apex of one or other of the triangles described. It should then be passed to either angle and into the opposite viscus, thus determining the base. Emerging at the point of beginning, the process should be repeated in an inverse manner from the opposite apex. The twine should then be tied. This was a most important part of the technique. Necrosis would not take place unless the pressure brought to bear upon the twine was of sufficient force to cause it to appreciably sink into the tissues. At least two centimeters should be taken up in this way. Having completed the tying of the stitch the Lembert should be closed anteriorly and the parts replaced in their normal position. The speaker illustrated his remarks by a lantern slide exhibition of drawings showing the technique and of specimens made at the Surgical Research Laboratory.

Dr. Lilienthal said that he had operated by this method for the first time six weeks ago. No vomiting had occurred and, although it had been persistent before operation, there had been none since the twine was introduced. The second case operated on involved a resection of the stomach and the union of the jejunum with a closed cardia. This case was unsuccessful. The third patient was operated on one week ago and had passed on to uneventful recovery. Dr. Lilienthal considered this to be a distinct improvement upon the technique of McGraw and believed that it would have a very low mortality rate if used in cases where the pylorus is not too extensively obstructed.

Dr. Joseph A. Blake congratulated Dr. Maury upon the success of his work at the research laboratory, and said that in the somewhat limited number of cases in which immediate opening was not necessary, he would infinitely rather trust to the twine than to an elastic.

Dr. Robert Abbe said it was refreshing to hear this report of successful experimental work. It seemed to him that it was only common sense to prefer twine to elastic ligature, and this was particularly so if the twine could be so placed as to cut out. This it could not fail to do if inserted by the ingenious method described. These open operations, he said, were always dirty and must have a higher mortality than a method by which absolutely no fecal material could possibly escape. He said that the time required to insert the triangular stitch was less than that needed to suture properly a Murphy button in position. A patient whom he had operated upon two days before had shown no signs of shock or other disturbance.

Dr. Willy Meyer said that if we could get rid of the elastic ligature and use twine, it would be a progress in the right direction.

Dr. Elsberg said that the McGraw should not be considered in any way a competitor of the Maury stitch, because the latter was such a radical improvement over the older technique. It punched out and this was the desideratum.

Dr. Lund of Boston stated that he had not used the method of the triangular suture or the McGraw ligature, because he was so well satisfied with the method of suture with clamps, introduced into this country by Moynihan, which he had employed in almost all his cases except ·se in which time was important, when the Murphy button had been used. He considered it a great point in favor of these methods that an immediate opening was made in the stomach and it was not necessary to wait for a slough to separate before feeding the patient. As compared with the McGraw ligature, the twine offered several points of superiority, the first being that a piece of the stomach wall was cut out instead of a longitudinal slit. The twine could be more easily applied than the ligature on account of its non-elasticity, and there could be no question of its varying in quality as was the case with the rubber ligature. Inasmuch as the triangle was the geometrical figure by which a space was inclosed in the smallest number of lines, it seemed to him that Dr. Maury had hit upon absolutely the quickest method of inclosing and cutting out a piece of tissue with ligatures. For it was evident on consideration that this could not be accomplished with a smaller number of sutures than those employed to make the three sides of a triangle. He believed that Dr. Maury's stitch was absolutely the most perfect which had yet been devised, of the methods which depended upon the cutting out of a suture to make an opening, and it was worth a trial in cases where it was not important for the opening to be established immediately. The absence of shock in the cases where the ligature had been employed, was certainly noteworthy, but it seemed to him hardly more noteworthy than the cases of gastroenterostomy in which the clamp and suture had been used according to Moynihan's method. The question of the field of gastroenterostomy as compared with that of Finney's operation, had interested him greatly. Finney's operation was a most excellent procedure. It certainly avoided all possibility of the vicious circle, as no loop was made, and, therefore, no circle formed. Technically, it was, however, somewhat difficult in many cases, especially those in which the pylorus could not easily be brought outside the abdomen. It was more difficult than gastroenterostomy, and the methods of placing the opening at the bottom of the stomach and other improvements of technique had practically put an end to the danger of the vicious circle. Gastroenterostomy was so easily and quickly performed, with absolutely no danger of soiling, everything being done outside the abdomen, and with no danger of wounding large blood vessels, that it was a little safer as a technical procedure than Finney's operation of gastroduodenostomy. The fact that in strictures of the pylorus there was no danger of bile getting into the stomach rendered it necessary to substitute Finney's operation for gastroenterostomy in these cases. Here the pylorus being closed, there was a steady stream of food going into the stomach from the gastroenterostomy opening, and the patients almost uniformly did well. Here also it was unnecessary to supplement gastroenterostomy by enteroenterostomy or closure of the ascending loop. In the other class of cases, viz., open ulcers of the stomach and duodenum, of which about 70 per cent. were located either in the pyloric region or the duodenum, it was desirable to divert the stream of food from passing over the open ulcerated surface. This was not done by the Finney operation. It might be done only by a gastroenterostomy, with, perhaps, enteroenterostomy and the other supplementary procedures mentioned. If this reasoning was good, the field for the Finney operation was greatly limited. In a gastroenterostomy, however, in cases where the pylorus was open, namely, those cases in which the operation was performed for the relief of chronic ulcer without stricture, the patients were sometimes troubled by the presence of a certain amount of bile in the stomach, which entered from the gastroenterostomy opening. Cannon and Blake had shown that in a gastroenterostomy with an open pylorus, the food passed out o fthe pylorus and up into the stomach through the stoma, forming a circle, a little passing down into the intestine each time until the stomach was empty. In gastroenterostomy for organic strictures of the pylorus, all operators had found that their cases did almost uniformly well. It was in cases where the operation was performed for the purpose of curing a chronic ulcer with bile in the stomach, that failure to cure, possibly a recurrence of the ulcer might occur. This

had been the experience of the Mayo brothers, who had been the leaders in the performance of these operations in this country. Moynihan seemed not to have had this trouble, or in fact trouble of any sort, with his operation, but nevertheless it was being recognized by operators almost everywhere as a real difficulty. To obviate the danger of bile in the stomach, enteroenterostomy was usually performed now in cases where the pylorus was likely to remain open. If enteroenterostomy and one of the various methods of closing or dividing the ascending loop, or even division of the pylorus, were performed, the time of the operation was somewhat prolonged, though not unduly in the hands of a skilled operator. In cases where these procedures were adopted, any time saving method like the one suggested by Dr. Maury, would be of the greatest benefit. An objection, however, to its performance where gastroenterostomy, enteroenterostomy, or closure of the ascending loop was required, was that the stomach was made a closed sac with no outlet at all until the stitches cut through, which would have been an undesirable state of things. In case Dr. Maury's method could be modified in some way, so that an immediate opening was produced, it would be a valuable procedure both as a time-saver and as a simplifier of technique. As it stood it was certainly an extremely clever device and one which would have a very definite value in cases where an immediate opening was not regarded as important.

Dr. Frank B. Gray said that in gastroenterostomy three things were essential: First, safety; second, simplicity; third, permanency. He believed that Dr. Maury had solved the first and third requirements, but he was not yet convinced that the method was as simple as others. Personally he had had good results with the elastic ligature, but he considered the employment of the twine as ingenious and deserving of commendation.

Dr. Warren S. Bickham said that he had not performed gastroenterostomy on the human being by Dr. Maury's method, but he had seen him introduce the twine on a dog at the Research Laboratory. He felt free to state that its introduction afforded no technical difficulties whatsoever, and that furthermore it was much more rapid than the technique of introducing a Murphy button.

Chicago Medical Society.

At a meeting held March 8, 1905, Dr. Daniel N. Eisendrath exhibited a case of "General Blastomycetic Dermatitis." Beautiful examples of the organisms of the disease were obtained from an ulcer on the patient's leg. The patient was a Bohemian, 40 years of age, and first noticed a small, circumscribed abscess which appeared upon the left side of the chest. Following this abscess, which healed after the use of medicine, patient noticed an ulcer forming upon the place where the largest ulcer existed at the present time, namely, the posterior surface of the right leg. The author pointed out the essential characteristics of the disease, and discussed at length the differential diagnosis of it from tuberculosis verrucosa cutis, from carcinoma, and syphilis. Dr. Eisendrath reported three cases of "Diffuse Septic Peritonitis following Appendicitis," and exhibited the patients. The patients were operated upon at a period ranging from twenty-four to seventy-two hours after the onset of the disease. In one of the cases perforation occurred into the free peritoneal cavity. He said the profession was indebted to one man for helping us to improve the percentage of recoveries in these heretofore very unfavorable cases—Fowler of Brooklyn. In his cases he resorted to the Fowler position, together with flushing freely with salt solution and drainage. Dr. Eisendrath also showed a well-marked case of "Hodgkin's Disease," and one in which he resorted to the Wolf method of skin grafting. He reported two other cases, one of encapsulated tuberculous peritonitis, and another of non-development of the testes in a man 30 years of age. Dr. Rosalie M. Ladova reported an interesting case of "Aortic Insufficiency" in a female. Of fifty-three cases collected by Babcock, there were only seven in females. Dr. Jacob Frank read a paper entitled "Complete Perineal Prostatectomy by Young's Technique," and reported two cases. The result in both was eminently satisfactory.

St. Louis Surgical Club.

At the stated meeting held March 8, 1905, Dr. Willard Bartlett read a paper on "A Simple Heat Method of Sterilizing and Storing Catgut." He said one year's work with catgut sterilized in the manner to be described, had been eminently satisfactory and bacteriological tests had proven the reliability of the process. The treatment of the raw catgut he described as follows. (1) The strands are cut into convenient lengths, say thirty inches, and made into little coils about as large as a silver quarter. These coils, in any desired number, are then strung like beads on to a thread so that the whole quantity can be conveniently handled by simply grasping the thread. (2) The string of catgut coils is dried for one hour at a temperature of 108° F., and then for a second hour at 220° F., the change in temperature being gradually accomplished. (3) The catgut is placed in liquid albolene where it is allowed to remain until perfectly "clear," in the sense that the term is used in the preparation of histological specimens. This is usually accomplished in a few hours, though it had been his custom to allow the gut to remain in the oil over night. (4) The vessel containing the oil is placed upon a sand bath and the temperature raised during one hour to 320° F., which temperature is maintained for a second hour. (5) By seizing the thread with a sterile forceps the catgut is lifted out of the oil and placed in a mixture of iodine crystals, one part in Columbian spirits (deodorized methyl alcohol), one hundred parts. In this fluid it is stored permanently and is ready for use in twenty-four hours; the thread is then cut and withdrawn. He found that this method caused the iodine to rapidly permeate the strands of gut so that the surgeon was assured of introducing an antiseptic as well as a sterile suture material. He had made a number of breaking tests and found that no other heat method produced a stronger strand.

College of Physicians of Philadelphia.

At a stated meeting of the Section on General Medicine, held March 13, Dr. Alfred Stengel reported "A Case of Tuberculous Meningitis following Trauma in a Patient Ill with Tuberculosis of the Kidney, and Giving a Positive Widal (Typhoid) Reaction." The patient was a brakeman, who had been struck in the back and again on the head, and was thought to be suffering from typhoid fever. He presented, however, marked incoordination in the movement of the eyeballs, due to paralysis of the oculomotor nerves, together with vomiting. In the fluid obtained by lumbar puncture a single tubercle bacillus was found, together with an increase in the polmorphonuclear leucocytes. There was a urethral discharge, in which gonococci were found. The number of white blood corpuscles was increased to between 13,000 and 19,000. Cultures of typhoid bacilli were agglutinated and rendered immobile by the blood serum. Cultures from the blood were practically sterile. Tuberculous meningitis being suspected, the skull was opened and the subdural space was flushed. Nothing coming away, the lateral ventricle was punctured, but no fluid escaped. Death resulted, and post-mortem examination disclosed the presence of tubercles at the base of the brain, together with meningitis, and also tuberculosis of one kidney extending into the ureter. Dr. A. A. Eshner exhibited the "Case of Congenital Universal Atrichia" that had been reported at the previous meeting. Dr. John M. Cruice read for Dr. A. P. Francine the report of a

"Case of Carbon Disulphide Poisoning." The patient was a man employed in an artificial silk works, where he was exposed to the vapors of carbon disulphide. He exhibited flushing of the face, with cyanosis of the lips, marked slowing of the respiration, and symptoms of peripheral neuritis simulating locomotor ataxia.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 1, 1905:

	Cases.	Deaths.
Measles	470	21
Diphtheria and Croup	317	31
Scarlet Fever	224	20
Smallpox	1	.....
Chickenpox	149	
Tuberculosis	413	172
Typhoid Fever	45	6
Cerebrospinal Meningitis	189	131
Typhus Fever		
Yellow Fever		
Cholera		
Totals	1,808	381

Spontaneous Gastric Fistula of Ulcerous Origin.—A patient of thirty-six years, operated upon by Jaboulay, had the following history: At the age of twenty, she first had trouble with her stomach. In the last five or six years, the pain had assumed all of the clinical characteristics of that of hyperchlorhydria and of ulcer. In May, 1904, the crises became more frequent, and at the same time there appeared a painful point in the ninth intercostal space, about 10 cm. from the median line. The skin at this point became thinner and ulcerated. From this time the pain disappeared, and through the fistula there flowed regularly gastric liquids, more or less abundant in quantity, according to the position of the patient. A posterior gastroenterostomy was performed with the hope of facilitating the cicatrization of the ulcer, and of indirectly drying up the fistula. For twelve days nothing passed out through the fistula, and then all became as before. At this time the patient entered Jaboulay's service. On July 20, he performed a median subumbilical laparotomy, connecting the fistula by a transverse incision. The wall, as is always the case in ulcer, was very vascular. The fistula was dissected throughout its course down to its gastric implantation, which represented the borders of an ulcer. Convalescence was comfortable. The fistula did not reappear, and on August 1, the patient left the hospital in excellent condition. Several points about the case are of special interest: A large gastric ulcer corresponded to a small cutaneous fistula; a radical operation is necessary when intervention is made in the case of an ulcer; gastrostomy performed through the intercostal spaces does not insure continency of the orifice.—*Lyon Médical,*

Nasal Obstruction and Mouth Breathing.—In an article on this subject J. S. Wallace states that the cure of mouth breathing should be carried out by the rhinologist *pari passu* with the treatment of the teeth and palate at the hands of the dental surgeon. In the treatment of the irregularities of the teeth dental surgeons recognize the important help to be derived from the laryngologist in the restoration of the functions of the nose, but all rhinologists do not recognize that some benefit might accrue from the expansion of the palate by the dental surgeon and by the restoration of the means of efficient mastication. Again, a most vigorous protest should be entered against the iniquitous and ubiquitous system of feeding children almost entirely on soft milk-soaked foods. Not because milk is occasionally the bearer of tubercle, scarlet fever, diphtheria, etc., nor because it leads to constipation, fermentation, and summer diarrhea, but because this pap system is the insidious cause of lifelong suffering from the numerous derangements of the alimentary canal which it brings on. It begins by producing the wholesale ruin of the teeth, together with many consequent troubles. It leads to adenoids and all the unfortunate sequelæ with which all are so familiar. Finally, it almost necessarily begets gastric insufficiency, malassimilation, and malnutrition, together with the general wreck of physical well-being which these derangements ultimately produce.—*Medical Press.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended April 1, 1905:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Florida, Jacksonville	Mar. 18–25	22	..
West Tampa	Mar 18–25	5	..
Illinois, Chicago	Mar 18–25	18	2

CEREBROSPINAL MENINGITIS—EPIDEMIC AND SPORADIC.

By GRANT GOULD SPEER, M.D.,
LOS ANGELES, CAL.

FORMER ASSISTANT PHYSICIAN TO THE NORTHERN MICHIGAN ASYLUM FOR THE INSANE AT TRAVERSE CITY MICH.

Cerebrospinal meningitis was first described by Vieussieu, at Geneva, Switzerland, in 1805, and it was first introduced into the United States at Medford, Mass., in 1806.[1] At first, both in Europe and America, it was purely epidemic in character; but since 1860, after having passed through a locality, especially a city, an epidemic has been followed by a varying number of sporadic cases, in a sense becoming endemic. The epidemics have been more or less localized, and when widespread the disease has not appeared exactly contemporaneously in the several localities affected, nor in an orderly sequence as to time, such as could be accounted for in the length of time required to travel along lines of commerce. So, in writing of different epidemics, individual writers are inclined to speak of them as they appeared in their localities, or, in a broader sense, as they appeared in a large city well reported, and no little confusion has arisen, and must necessarily arise in fixing the dates of the epidemics of a disease so erratic in its course through the body politic. It is best described by Dr. Osler[2] as outbreaks occurring in waves, the crest of the fourth for the century breaking over the United States in 1898-9, appearing in twenty-seven States, abating in 1900.

It was this wave that swept over Michigan, but that the soil was fully in readiness for the disease germs was evidenced by the increase of sporadic cases that appeared throughout the summer of 1898. The papers had chronicled here and there a death, and text-books described the disease; but sporadic cases had been so infrequent, the time was so remote from the last epidemic, the profession had come to look upon it as a rare disease, and the impressions of its character and terrible ravages were lost, when, like a foe from ambush, it struck community after community, all too unprepared to meet its terrible onslaught. While the result of any widespread epidemic is heartrending and the losses irreparable, there was much gained in this epidemic in the investigation and fresh literature of this disease, preparing us for the increase of sporadic cases and smaller epidemics that have necessarily followed.

Why this disease appeared at this particular time, from whence it came, its predisposing causes, its fundamental principle, how this enters the system, and the degree of its infection have been questions open to investigation and argument. The first of these has not been satisfactorily answered. Appearing in this country the year following its recognition in Switzerland, a country from which we have no great amount of direct commerce or immigration, its method of introduction is not made clear. Appearing as a pure epidemic in both Europe and America until 1860, since which time it has been endemic in the more congested centers, the relationship between one epidemic and the one following, between the endemic sporadic cases to the next epidemic, or between epidemics existing contemporaneously in two places, has not so far been clearly shown. For the second, air, earth, water, relation to other diseases, sex, age, social relations, and personal contact have all been more or less considered with but little better result. In only exceptional and obscure cases have the circumstances pointed to the disease having been carried by travel. All classes of people, and even animals, both domestic and wild, have been affected. While the greatest number are children, persons of all ages have been attacked, from the babe in utero[3] to individuals above threescore years.[4] There appears to be but little discrimination in sex, the males perhaps leading, through greater hardship and exposure. There was an epidemic of influenza early in the winter of 1898, but it must be remembered that this was preceded by sporadic cases of cerebrospinal meningitis, the forerunners of the epidemic. So widely was this disease disseminated that it was reported from New Orleans to Minneapolis, and from Boston to Salt Lake, and covered a great variety of climate, elevation, soil, and water supply. The winter was long and tedious, the temperature of its later months reaching a point lower than had been recorded in years, and the spring, into which the epidemic extended, was cold and backward; people were confined closely in ill-ventilated and superheated houses, and when forced abroad, the discomforts of exposure were accentuated by contrast of indoor and outdoor temperature. With a superabundance of food and heat, and a minimum of sun and exercise, and with a resulting sluggish circulation, the physical resistance to disease was reduced to a very low point. Similar atmospheric conditions, yet more severe, prevailed in 1903-4, and again there was an epidemic severe enough to cause unusual comment. A late authority[5] states that this disease usually occurs under those conditions that produce pneumonia. A broader statement of this principle, while recognizing the close relationship in the character of these two diseases, is that it occurs under those hygienic conditions that reduce the physical condition to the point that makes it most receptive to infection in general. Besides meteorological conditions, predisposing causes include physical fatigue, mental worry or excitement, crowding, poor food, and other unsanitary conditions. While it may be brought forward that many of the victims were stalwart men, apparently in fine health, it can usually be found that some untoward condition or circumstance had a depressing effect upon the general vitality. This disease may occur in summer, but, like many other epidemic diseases, it is more prevalent and fatal in winter. The effect of air currents has received but little attention, and in searching for the medium of transmission of this disease, it must not be overlooked that in cultures the bacterium now looked upon as its cause is short lived, but

that "Germano found that it resists the destructive action of dessication and preserves its vitality even as long as ninety days." "Neisser has shown that the organism is transportable by atmospheric currents, even the most feeble, and that it is very susceptible to aërial convection." By this last clause we understand that there may be a transportation of these germs through the air, independent of its currents.

The fundamental principle of this disease was long suspected to be a bacteriological one, and its investigation has been earnest and thorough. To give even the present day aspect of this research would unduly lengthen this paper. Various organisms at different times have been selected as the exciting cause, and even now mixed infections are credited. The whole investigation is covered by the history of the group of encapsulated bacteria, early represented by the bacillus of Friedlander, of which the *Diplococcus intracellularis meningitidis* has been generally accepted in the two last epidemics—1898-9 and 1903-5, as the cause of the epidemic form; but that of the sporadic appears to be still under advisement. The distinction between an epidemic and a sporadic cerebrospinal meningitis cannot be accepted as conclusive, as it is based upon negative rather than positive testimony, the case being termed epidemic when the specific germ is found, and sporadic when it is absent. Osler states that early in the disease *Diplococcus intracellularis* is alone present in the cerebrospinal fluid, while later the fluid may be sterile or mixed with pneumococcus, pus organisms, and bacillus coli communis. Both he and Soerensen[6] found tubercle bacilli in instances of an acute disease grafted upon a chronic one. The weight of evidence, negative and positive, confirms the belief that sporadic cases are simply isolated manifestations of the condition that obtains in cases occurring epidemically, the cause of both being identical, though perhaps varying in attenuation and virulence; but as the sporadic cases appear in no great numbers, and the opportunity for investigation is less, even this exception is not well taken.

The mode of entrance of the germs into the system is still under investigation. Some argue for an entrance through the bowels, because of the accompanying dysentery,[7] and others contend for an entrance through the Schneiderian membrane,[8] because of a coryza. The latter view is well sustained by the proximity of the nasal cavities and the base of the brain, similarity in delicacy of this membrane and the meninges of the brain, the easy mode of entrance at this point through the blood supply, lymphatics, and nerve sheaths, and the great activity of the disease at the base of the brain, near the supposed point of entrance; but in the cases I have seen, the secretions (early or late) in the disease were not much disturbed; there was no coryza, and the bowels were inclined to be constipated.

That such an organism as *Diplococcus intracellularis* is infectious cannot be doubted; but there are various degrees of infection, and many diseases we know to be infectious we term non-contagious, because the chance of a person taking them by coming in contact with the patient is so slight it can be well left out of consideration. Of such diseases are true lobar pneumonia and cerebrospinal meningitis. Of the two, the latter is doubtless the less infectious through the active manifestations of the disease being isolated within the bony structure of the skull and spine, and the minimum amount of secretions from the seat of disease. The most casual observer has noted the large number coming in contact with the disease under all conditions, and none contracting it, and nearly all authorities, while noting exceptional cases of two or more in the same family, or where the disease has been apparently carried between two localities, are quite agreed that, in the true sense, it is not contagious. All excitement regarding the spread of this disease should be carefully and firmly allayed to remove fear as a predisposing cause and prevent any hysterical simulation.

I have nowhere seen mentioned cerebrospinal meningitis complicating surgical and puerperal cases. Three such, of a sporadic form, have come under my observation, all of which terminated in death. The first of these, a robust and otherwise healthy girl, was operated upon for appendicitis by a very competent surgeon. She was progressing finely, when the brain and spinal symptoms suddenly developed, and by the time her physician could reach her she was in a dying condition. A short time later the same gentleman had a case of confinement at term, and in about three days the woman developed a typical case of cerebrospinal meningitis and died after several days of illness. The third case appeared in the writer's own practice, removed from the other two by several months, from December, 1901, to September, 1902. A short plethoric young German woman had had one child, and later an abortion at six weeks. She expected to be confined again about November 11, 1902. She had no kidney trouble, but suffered much from headache and ill feeling during gestation. She took to bed September 13, and the next day gave birth to an immature female babe that died. The placenta was adherent and removed by force. On September 15 she developed fever, which, after a curettage and douching, was absent two days later. The right breast then became swollen, giving trouble for a few days. Visits were discontinued on September 23. The woman got up about the usual time and at least once visited my office. While there seemed nothing radically wrong with her, she did not recover her buoyancy and suffered from headache. I was called to the house again October 10, when she had a severe headache, and in forty-eight hours she developed a typical case of cerebrospinal meningitis, with moderate opisthotonos, gradually sank into deep coma, and died October 21.

The seat of this disease, the meninges of the brain, is supplied with arteries and veins, and the cerebral fluid has a circulation similar to the lymph in other structures.[9] As might be inferred, therefore, the diplococcus and attendant bacteria behave very much as in an infection of the areolar tissue of other regions, making due allowance for greater delicacy of tissue involved and character of adjacent organs. This disease, then, may be divided into five stages—incubation, invasion, congestion, effusion, and pus formation—any one of which may be aborted, modified, merged into or become contemporary with the others through gradual extension of the disease. The period of incubation, from the reception of the germ into the secretions or tissues of the body until the beginning of proliferation, has not been determined, as it is attended by no physical manifestations. The stage of invasion, from the first proliferation of the pathogenic bacteria or their spores in the tissue of the body until by their number or toxins they produce a disturbance of the circulation, is somewhat better marked than the other; but doubtless it is variable, being very short in the fulminating cases, and extending over days and weeks in the insidious.

The stage of congestion is characterized by physical changes noted post mortem. In cases that survive but a few days after the onset of the disease there is hyperemia of the arachnoid, which may be

shared by the other meninges, or even the blood-vessels of the brain itself showing as punctata vasculosa[10] on section. The records appear silent on this point, but it may be accepted that the stark, swollen tissues of this stage are characterized by a lessening of their natural secretions, as in other septic conditions, and that the gross amount of cerebrospinal fluid is diminished. But as the fight between the forces of the body and the bacteria goes on, the exudate which is a characteristic of this disease appears. The distended blood-vessels overflow, the lymphatics become engorged, and in response to the irritation engendered, the serous element throws out a superabundance of fluid, and the tissues become swollen and sodden. As may be supposed, the greatest amount of effusion is at the seat of the beginning of the disease, and often of its greatest activity, the base of the brain and ventricles, where it works further mischief by mechanical pressure. The irregularity of the cavity of the ventricles favors the retention of any fluid it may contain. It contains, besides a diaphanous epitheliated lining, a process of the pia mater, the velum interpositum, a highly organized cellular tissue, along the border of which is a fringe-like vascular process, the choroid plexus.[11] This enters the ventricles through the transverse fissures, and by its connection with the lining of the ventricles excludes them from the outer brain. In health, besides giving nourishment to the ventricles and adjacent parts, this process no doubt removes their fluid and débris, but under inflammatory action its powers of absorption are paralyzed, and the swollen edematous membrane impedes the little drainage required by the ventricles under natural conditions. This effusion may soon take on a purulent form, varying from a few white blood cells mixed with fibrin pervading the serum, to a thick, smeary coat of pus lining the ventricles, or a mass as thick as butter, with little or no fluid.

During the changes described, adhesions are formed between adjacent portions of the brain, the meninges are thickened, the convolutions flattened, and the sulci deepened. The substance of the brain is softened, and, with the cord, primary and secondary changes occur. Adjacent organs may suffer; thus there is a degeneration of the auditory nerve, and deafness is commonly reported as a sequel to this disease. And, while there is doubt as to pus following the course of the optic nerve, it has been found within the eye to such an extent as to fill the globe, pushing out the vitreous and perforating the cornea. It must not be taken for granted that all parts of the brain, cord, and adjacent parts are attacked simultaneously; on the contrary, clinical indications point to a more or less gradual extension of the disease process from one part to another until it is checked by self-limitation, when absorption of the pathological fluids is well instituted and resolution gradually takes place.

Important changes occur during the course of the disease outside of the central nervous system. Among the most noteworthy of these is that which takes place in the blood. This arises partly from the inflammatory processes and partly from the inherent character of the disease. The greater the blood changes, the greater the liability to fatal results. The most common appearance of the blood at post mortem is its dark color with unusual fluidity, and the presence of soft blood clots. Gas bubbles and a rapid decomposition of the blood when drawn from the body have been noted. Erythema or ecchymotic spots form upon the skin and mucous membranes, and may break down to form sores. This appears to have occurred more often formerly than in the later epidemics, and gave the name of spotted fever to the disease. These indicate the most profound alterations of the blood and the most malignant type of this malady. Toxins are formed, probably with the beginning of the hyperemia of the meninges, and sent adrift into the system, and later may be augmented by those of a mixed infection. *Diplococcus intracellularis* may be found in the meningeal fluid, but the organisms are mostly confined to the cells of the meninges, while the *Micrococcus lanceolatus*,[12] when present, is quite generally distributed throughout the body, and pus and other organisms may be distributed by metastasis. Various organs of the body undergo degenerations, but these are not uniform in character, and are rather an effect of inflammatory action and blood changes than a part of the disease.

For convenience we may recognize two forms of the disease—the insidious and the fulminating. This division is wholly arbitrary, there being no difference, except that in the first the pathological conditions follow each other in such orderly sequence as to allow an analysis of their effects and attendant symptoms, and in the second, like the pictures in a kinetoscope, they follow each other with such rapidity that they seem to form a composite whole. While the diagnosis at a certain period of the disease may not be easy, because of the mild, unobtrusive nature of the insidious variety, or the furious character of the fulminating, the symptoms from the beginning to the end, whether covering several weeks or occurring in a few hours, form a fairly classical whole. Many writers speak of the beginning of the invasion as characterized by a coryza, diarrhea, chill, projectile vomiting, convulsions, or a sudden onset of a storm of symptoms. All of these are present in a representative number of cases; but no one of them occurs in a majority, nor is any of these necessary to mark the onset of this disease. The initiatory symptoms most common are malaise, uneasiness, general discomfort, and a sense of impending harm, with shifting pains in legs and back. These are followed by headache, which is marked in this stage, and usually remains through the others until lost in delirium and coma. In fact, headache seems to be one of the most constant symptoms, and in the presence of an epidemic all headaches should be regarded with suspicion and be carefully watched. The headache usually occurs at the apex and base of the brain, and is accompanied by photophobia. The pain quickly passes down the back, the neck stiffens and sometimes exhibits a spasmodic contraction of its extensors. The headache is increased. There is a tendency to somnolence, but as long as the patient is conscious he is kept awake by the pain. Through semiconsciousness and delirium, and even when the patient is oblivious to his surroundings, indications of pain continue until convalescence is established or the patient is too weak or profoundly unconscious to give expression even to the reflexes. The pain may be constant or intermittent, and is liable to be excruciating in character, and the patient expresses his torture by a restless movement of the member in distress, or a throwing about of the body and the uttering of sharp animal cries with each exacerbation of the muscular contraction. Even convulsions supervene. The patient is extremely hyperesthetic, and is sensitive to touch, jars, light, or noise, and when at all conscious is fretful and exacting. As weakness progresses sordes gather upon the teeth, the lips become sore from herpes, and eruptions of a nervous origin, similar to herpes zoster, may appear upon the limbs and body.

The stiffening of the neck is the beginning of the opisthotonos, and unless the pain and muscular contracture are relieved, the head is gradually drawn

back until the occiput rests upon the cervical vertebræ, and gradually the whole spine and lower extremities become involved, so that, in extreme cases, a line from the occiput to the heel will form a true arc; but, unlike hysteroepilepsy, the patient has no power to rest on head and heels, but reclines on the side, with a tendency to turn the face into the pillows.

The stiffening of the neck no doubt also marks the beginning of the effusion in the brain and the extension of the disease down the cord, as in the slowly developing cases it may not appear until several days after the onset of the disease. It is about this time that other signs of pressure occur which at first are not fixed in character or constancy, except two. These are the sign of Kernig, which has always been found when looked for, and another, not named, which, I believe is closely related to the other, is quite as often found, and appears among the early symptoms of pressure. This is a turning in of one or both feet until, if not disturbed, one lies across the other. The legs at first are extended, and may continue so, taking part in the opisthotonos; but usually sooner or later they become flexed and join with the feet in the tendency

Case seen in consultation with Dr W. A Sickles. Male about two and one-half years, youngest of three children, all attacked, this and a brother simultaneously following older sister. The boys fully recovered. Observe the retracted head bowed back, flexed legs, and crossed feet. Ecchymotic spots were numerous over all of body and some broke down producing ulcers.

to cross each other. The pupils usually become widely dilated, but may be contracted, or one contracted, the other dilated. Groups of muscles become useless; it may be the part of one arm, or one leg, or the upper and lower extremity on opposite sides, the muscles of the throat, bladder, or rectum.[13] There may be incontinence or retention of urine, or one condition may follow the other. Constipation is the rule, but diarrhea may occur. It will be seen that any set of muscles is liable to become affected without regard to any others. This paralysis may wholly pass away, be transferred to other sets of muscles, the first recovering, or, as shown below, it may become permanent, causing atrophy and impairment of the part. Paralysis of the throat or those parts of other vital functions may hasten death.

From the first of the invasion there is a mild febrile movement, which is variable, according to the disposition of the patient and the character of the onset. At the most acute stage about 103° F. marks the height of the attack, but it may be as low as 101° F., and may rise to 106° F. The pulse rate is increased, but does not follow the fever curve. This high temperature is likely to subside gradually, remaining higher in the evening than in the morning. But with the drop in temperature there is not a corresponding drop in pulse rate, which, though increased in the fever of the acute stage, is still higher in the subacute or chronic, when the temperature may be normal or subacute. The respiration is usually regular, but may be quick and jerky, and is often accompanied by a groan at each expiration. As the weakness progresses the respiration becomes very shallow, and if pneumonia, either static or acute, occurs, the respiration will take on the character of the complication.

It has been specifically pointed out that there is an intermittent type of this disease, but in nearly every case, whether of an intermittent type or not, after it has progressed and signs of pressure have occurred, there is an intermission, in which there is an improvement in all symptoms, and it would appear that convalescence was about to take place. This is soon followed by a relapse, in which the opisthotonos reappears, and symptoms of pressure and paralysis of muscles have a tendency to become permanent. We have a pretty fiction that this remission is caused by an escape of fluid from the third to the fourth ventricle, but more probably it is caused by changes in fluid and surrounding tissues similar to that in a phlegmon in changing from an edematous condition to a purulent one, a pointing, so called.

From this stage the disease takes on a subacute or chronic form. The temperature falls to normal or subnormal, with occasional rises marking the appearance of acute symptoms. The respiration is more slow and feeble, and the pulse continues or is increased in rapidity. The restlessness or delirium sinks into deep unconsciousness; the pupillary reflexes are abolished, the eyes set, and opisthotonos and paralytic conditions increase. Death occurs through exhaustion, inability to take food, toxin poisoning, or convulsions.

If, instead of a fatal ending, convalescence takes place, there is a gradual lessening of pain and restlessness and of the opisthotonos. The child presents a weakened, miserable condition, with now and again acute symptoms of relapse, and perhaps after days and weeks it appears free from the disease, but is too feeble to make an effort to arise, and even after being about the house for months, it shows a weakness of the back, has a shambling gait, and falls down easily. Previous epidemics have left in their trail many deaf, blind, halt, and imbecile, but of those cases coming under my observation in the acute stage, I have seen no mental impairment, and but one of paralysis that was persistent. This resulted in a clubfoot, which I later relieved by a radical operation.

All have agreed that this is one of the most fatal of the acute febrile diseases, but the rate of mortality has been variously estimated. Dr. J. Lewis Smith states that up to 1872, of the 52 recorded cases, one-half died. Since 1872, of 38 cases, 18 died, or 47 per cent. Osler gives a mortality of 25 to 75 per cent., and of the 23 admitted to his wards in Baltimore in 1898-9, 9 died, or more than 39 per cent. He also quotes Hirsch, in his statistics of 15,000 cases at 37 per cent. Jos. W. Irwin gives a death rate as follows: In the winter of 1873-4, 60 per cent., followed in the living by many crippled and mentally impaired; in 1877 the rate is not given, but he remarks, "Nothing different from the first was observed." In 1898-9 he gives his mortality at 30 per cent. at Louisville, Ky., while reports from the southern part of the State showed a mortality of 80 per cent.

The conditions in the State of Michigan were probably well represented by the local conditions at Manistee, where I was located during this epi-

demic. Thirty-four cases were reported to the Health Officer, to which 2 more should be added that were not recognized until after death, making a total of 36. Sixteen died, a mortality of 44 4-9 per cent. In Eastlake, a suburb with its own health officer, there were 11 cases, surrounded by unsanitary conditions; 3 died, or 27 3-11 per cent. Ten of the eleven were treated by Dr. W. A. Sickles, now of Milwaukee; of these, two died, or 20 per cent. I saw some of these cases in consultation, and they were of the most malignant type I have encountered. Some idea of how malignant they were may be conveyed by the illustration, taken from a photograph of one of these cases that recovered. Dr. H. D. Robinson gave a mortality of 16 2-3 per cent., and my own was the same for the city and suburbs during the epidemic. I have since had three sporadic cases, one of which ended in death.

The general death rate for the epidemic of 1898-9 was placed at 50 per cent., and in the increased epidemic conditions of 1903-4 the reported mortality is again placed at 50 per cent.

The greatest mortality is among children. "The aged are rarely affected, but a few cases occurred in persons over sixty, and they all died." The fulminating cases are more fatal than the insidious, and it has been found true in both forms that the greatest number of deaths occur in the early period of the disease, *i.e.* if the patient can be carried along until the symptoms of permanent pressure appear, the disease is more liable to take a subacute or chronic course, with greater hope of recovery. However, in any case the prognosis must be guarded, as many cases ushered in as fulminating soon take on a chronic form and recover, while others have a mild onset and rapidly grow worse, in spite of all efforts to establish a convalescence; or still others with a good prospect of recovery, after a tedious illness, die of exhaustion.

The treatment of acute cerebrospinal meningitis is both surgical and medical. And if a further trial confirms the results obtained by Dr. Wolff of Hartford, and later by Dr. Waitzfelder[14] of Gouverneur Hospital, New York, in the use of diphtheria antitoxin in this disease, we are perhaps not only at the beginning of a new method of treatment, but also a change of view regarding the exact bacteriological cause. The surgical treatment, which is usually accompanied by internal remedies, as in other septic conditions, consists of the abstraction of a portion of the cerebrospinal fluid from the spinal canal through a puncture or an incision, after which local irrigation or medication of the spinal canal and its contents may be instituted. This procedure, made possible by aseptic surgery, and familiarized by experimentation in spinal anesthesia, and suggested by its employment in other meningeal troubles, is best performed after the method of the lumbar puncture of Quincke. As a remedial measure much has been expected of it which has not been realized, though there are those who are enthusiastic in its use. The status of lumbar puncture has not materially changed since it was written upon in a general way by Browning[15] in 1894, which is summed up as follows: Without danger, one to one and one-half fluid ounces may be abstracted; in internal hydrocephalus the relief is but temporary; in tuberculous meningitis it is not worth the trouble, and there is no positive indication for it except as an aid to diagnosis.

The reason for this disappointment lies in the fact that it is not applicable to all cases, nor to those conditions in which the changes are most rapid and dangerous, and is only partly effective in those cases to which it is applicable. In spina bifida and other malformations or injuries of the spine it is considered a serious accident to drain the meninges of any great amount of fluid, hence we should extract fluid with care during the period of invasion, or that of congestion, in which the secretions are already diminished. We are then limited to the periods of serous and purulent effusion, when the secretions are superabundant; these occur when the disease is well under way and the zenith of danger has been reached or passed. Choosing the period of serous effusion for our puncture, we have no means of knowing that the disease extends so low in the spinal canal, and we may have the phenomenon of diseased fluid being drawn through healthy tissue. If no harm be done by extension of the septic condition, the serous fluid is quickly replaced, and the relief from pressure is but temporary; while on the other hand, if the drainage can be made complete and continuous, the tendency to more and firmer adhesions between the diseased parts is increased, as is shown in widespread areolar swellings that cannot be excised and are unwisely incised.

In purulent conditions, according to the old dictum, "when there is pus evacuate," it is theoretically indicated. Koplik,[16] who has had extensive experience with lumbar puncture, points out that it relieves the symptoms of pressure, and, judged by rational symptoms, it is indicated when irritability is great and headache severe, but it does not cut short the disease, does not prevent relapse, and is inefficient in extreme retraction of the occiput, rigidity, and even opisthotonos, and that in these cases it has been shown there is danger of sudden ventricular dilatation, a condition where lumbar puncture is most called for and fails. He thinks it has not produced the death rate, and quotes Seager on mortality and treatment, as follows: Simple lumbar puncture, 20 cases, 9 died, 45 per cent.; in the treatment by baths 60 per cent. died; lumbar puncture, followed by injection of 1 per cent. lysol, 31 cases, 13 died, 42 per cent.; injection of oxycyanide of mercury, 7 cases, 4 died, 57 per cent. In Oporto, where the epidemic showed a mortality of 62 per cent., 26 cases were treated by simple lumbar puncture and 8 died, 30 per cent. This failure to treat the purulent stage successfully by surgical means appears to me to rest upon the intricate anatomical relations of the parts of the brain affected and the site of the puncture, together with the inefficient drainage provided by a small aspirating needle. In some future time, when surgery of the central nervous system has been placed upon the same safe plane as abdominal surgery, we may insist upon more thorough drainage of the base of the brain, or at least, as Dr. Jacobi[17] suggests, but does not recommend in internal hydrocephalous, a direct drainage of the ventricles by a trocar introduced at the location of the anterior fontanel.

Incision of the spinal canal has been less extensively practised than puncture, and has not given as good results.

While nothing but praise should be given investigators for their work along this line, and every assistance given them for future endeavors, we are obliged to conclude that under present conditions of our knowledge of surgery of the central nervous system, lumbar puncture for the treatment of cerebrospinal meningitis has not been of such unqualified success as to recommend it to the busy practitioner or surgeon as a means of reliable routine treatment, but rather he must be warned that it is still in the experimental stage, with many points to be perfected.

The medicinal treatment, apparently, has been hardly more satisfactory than the surgical. Dr. Henry Hartshorne[18] in 1881 begins by saying, "We

must lament the unsatisfactory condition of the evidence of this subject," and ends with, "but more positively successful evidence is needed to give the profession much confidence in the treatment of this affection." Dr. J. C. Wilson, May, 1896, says that "it cannot be a matter of surprise that the treatment of this disease has been almost as various as its form. To this unsatisfactory state of affairs the personal views of practitioners and the phases of fashion in therapeutics have each contributed an important share." An editorial writer in the *Journal of the American Medical Association,* June 4, 1904, says that "the treatment of this disease so far has not been satisfactory." What can be more discouraging and depressing? With such direct evidence sustained by statistics of mortality that, while there has been splendid progress in the investigation that has cleared up much of the mystery of this disease, very little has been made in its treatment, it is little wonder the average physician looks upon it as suitable only for expectant treatment, and the more timid or less experienced are inclined to abandon the case upon the appearance of grave symptoms, thus unnecessarily raising the death rate.

It is always the attitude of the profession to class as presumptuous the basing of a plan of treatment upon a small number of cases, and many men who have had unusual success in treatment have ascribed it to coincidence or a milder form of the disease, and have modestly refrained from pushing their claims, no doubt feeling that the ground had already been well covered by those of larger experience. This disease has the peculiarity, even in widespread epidemics, of attacking but a small percentage of any one community; the patients are thus divided among the various practitioners, each one treating but a few cases. It is upon an assembling of these we base our statistics of mortality, and it is upon this we must found a common mode of treatment if at all.

With something of a knowledge of the treatment of meningeal troubles in general, and the unwritten history of methods successfully employed in the early 70's, again successfully put in practice in the year 1898-9, I wrote the following: "In the treatment of cerebrospinal meningitis four principles may be arbitrarily laid down, viz., relieve the pain, clean out and keep clean the alimentary tract, draw away the blood from the nerve centers, especially those which are included in the base of the brain and medulla, and cause the absorption of the inflammatory products as soon as they are found to be exerting pressure upon the nerve centers. The nearer these rules are observed, by whatever means, the greater success shall we have in combating this disease."

After a somewhat more extended experience, a further consideration of the pathology and symptoms of this disease, and a comparison of the treatment then advocated with that of those showing a low death rate, there appears to be no reason for one to recede from this position. As this disease is most acute in its inception, profound in its effects, and subject to sudden changes in character, no brilliant results may be expected unless the treatment be most energetic and thorough, uniformly faithful, and marked by the exercise of good, but not dilatory judgment. By this it must not be inferred that one must try every one of the drugs indicated until a suitable one be found, but after a selection is made for the case in hand, the remedies must be pushed until the result desired is obtained, and continued until they are positively no longer indicated.

The relief of pain is of the first and vital importance. The fallacy of the saying that pain never kills is shown in the disturbance of a plexus or ganglion, or the prolonged irritation of the peripher-

ery, causing shock, exhaustion, mental prostration, and death, whether it be interpreted by the brain as pain or not. Besides causing the effects directly, such disturbances, pain (conscious or unconscious) may cause them indirectly by causing distortions and otherwise disturbing the natural relations of the parts of the body and their functions, *e.g.* opisthotonos disturbs the circulation of the base of the brain by changing the relative courses of the different blood vessels of the neck, and when severe it causes direct pressure of the skeleton upon the medulla and the beginning of the spinal cord, increasing the tendency to paralysis or coma, and hastening death; it interferes with respiration and the action of the heart, and with the general nutrition by placing the nerves and muscles upon the stretch, thus seriously interfering with their function. Then by all means place the patient beyond the point of suffering. The amount of sedatives a patient in the agony of this disease will tolerate is marvelous. Opium was by far the favorite of the early American physicians, who did not hesitate regarding the size of the dose used. Dr. J. C. Wilson says, "It is to be employed at the earliest moment in full doses," and proceeds to quote Strong, who gave forty drops of laudanum every hour; other physicians gave gr. xxx to ʒi of the crude drug; Chaufford, gr. iij to gr. xv; Bouden, gr. viiss at the beginning, and gr. i to gr. xi every half hour. "As the symptoms abated and the patient became drowsy the dose was diminished." These large doses were frequently followed by recovery. Coma was not considered as a contraindication. In the epidemic of 1898-9 Dr. Jos. W. Irwin, in his remarkably low rate of mortality, apparently relied upon morphine to relieve pain and vomiting, prevent mental complications, and perhaps arrest serous effusions, giving it hypodermically in doses of gr. 1-3 to gr. 1-4, repeated at intervals of a few hours. As the exudate appears opium loses its utility and must be given more guardedly. Potassium bromide, alone or with large doses of ergot, has been recommended, together with chloral hydrate as an emergency remedy. Objections to these remedies will at once suggest themselves; in the opium of deranging the secretions, and in the bromide, alone or with chloral hydrate, of not being rapid or profound enough in its effects. On reaching the bedside, the most certain and convenient method for relieving the suffering will be a full hypodermic injection of morphine, combined with atropine. But because of its cerebral stimulation in some, its uncertain action in children, and its tendency to produce constipation, it cannot be universally nor continuously employed. A sedative that overcomes these objections, and from which no harm has arisen, even in large doses, is as follows:

℞ Potassii brom..... gr. cxx
Chloralis hyd..... gr. cxx
Cannabis ind..... gr. j
Hyoscyaminæ ..... gr. j
Elix. simplicis. q. s. ad..... ʒj
M

This is sold ready prepared by various manufacturing chemists and may be compounded by the physician himself. Of this, a child of three is given ten to fifteen drops every twenty minutes until profoundly under its influence, and it must be repeated as soon as there is either moaning or restless movement of the limbs. The dose for an adult is one-half of one teaspoonful administered in the same manner. The attendants should be frequently admonished not to let the patient suffer, else through fear of "drugging," much suffering and danger to life will follow.

The treatment of the bowels seems to have received but little consideration. But an initial cleansing of the alimentary tract in all acute diseases and especially in eruptive and zymotic fevers has become classical and holds equally good in this. The logical remedies are full doses of castor oil and calomel. Anything like a prolonged or severe catharsis is to be avoided, but a dose of calomel, occasionally repeated, is often followed by improvement of the symptoms. When calomel is no longer indicated constipation may be overcome by any mild remedy suitable to the case which will readily suggest itself.

To divert the blood from the nerve centers the nature of the onset of the disease indicates active purgation and blood letting, but in practice both are to be condemned because of the asthenic condition of the later stages and the prolonged convalesence in which the recuperative powers are not able to meet the changes wrought by the disease, nor to supply the parts abstracted by catharsis or lancet. Venesection is further to be avoided in children because of the marked untoward effect often following the abstraction of even a small amount of blood. We have then for the equalization of the circulation the application of cold, heat and counterirritation, all of which are useless unless applied systematically, vigorously, and thoroughly throughout the course of the disease. The hot pack, warm and hot baths, hot sponging of the back, direct heat, hot mustard foot baths, leeches behind the ears or on the temples, dry and wet cups, and blisters to the back of the neck and occiput, the general application of mustard, of salt and hot whisky, of red pepper and brandy, or mildly stimulating lotion along the spine, as camphor oil and turpentine and the ironing of turpentined woolens over the spine with hot irons are some of the means recommended. These are all good according to the amount of surface affected and the amount of blood forced into the general circulation, especially of the periphery. In the use of blisters and counterirritants there is nothing gained by deep effects, but rather whatever procedure is instituted, it should be one that can be continuously applied with least disturbance of the patient. My method has been to apply half strength mustard plasters from the nape of the neck to the heels and bottoms of the feet; a ventral application also would no doubt add efficiency. These are left on until the skin is well reddened, which is healed as fast as possible with vaseline or cold cream, and the mustard reapplied, thus ensuring an active sinapism without blistering. Ice applications and cold sponging to the spine have been tried in a small number of cases, but have not received extended favor. Ice to the head in this and other acute cerebral affections is one of the tried and true therapeutic measures used by many practitioners. The ordinary ice bag applied in the usual way is worse than useless, a means of annoyance with no relief. To be efficient, the pounded ice must envelop the head above a line drawn from the brow to the hair line at the nape of the neck; and the application must be continuous. The most effective method is by means of the ice helmet to be tied under the chin; but this may be improvised by wrapping the crushed ice in a layer or two of cotton cloth and one of flannel, laying this in a shallow receptacle of rubber sheeting. As a matter of convenience the crushed ice may be mixed with coarse bran. A few patients cannot stand the application of ice on account of the liability to chill, or congestion of the bronchi and lungs; but to most it is very grateful after the first clammy sensation has passed away.

As soon as the first intermission has occurred or signs of pressure are established, means to absorb the morbid products are to be instituted. The agencies already enumerated, directly or indirectly, have this as a part of their functions and should be continued; but at this point they need the reinforcement of something more specific. As may be suspected the mercurials have been largely employed but have received no great amount of favor, except calomel, which is probably due to its action on the portal circulation and antiseptic action in the bowels. Dr. H. D. Robinson had good results from the protoiodide through its combined effects upon lymphatics and bowels; further than this I do not know of its use. The only remedy found to meet the indications of acting upon the glands has been straight saturated solution of potassium iodide in the relatively heavy dose of three to five minims every three hours to a child of three years.

This covers the cardinal points of treatment, but the minor details are none the less essential to the recovery of the patient. The nursing is that for the long debilitating fevers; the room shall be large and well ventilated, the bed must be moved from the wall so that attention may be given with the least disturbance to the patient, the bed clothing at all times clean, smooth and well aired, the light subdued but not darkened, and all noise and confusion avoided. The skin, mouth, nose and eyes should receive frequent attention by cleansing with water or mild antiseptics. The kidneys and bowels are to have the most careful attention to correct any incontinence or retention. Diarrhea may be checked by any of the usual aromatics, astringents or preferably the opiates; suppression of urine relieved by heat, potassium acetate, sweet spirit of niter, and of course the exhibition of physiological salt solution per rectum. Water is to be given freely. The diet for the acute stage should be light, even scanty, but as the fever abates, or if it is prolonged, though still liquid, the diet should be more nutritous and frequently administered.

For the fever quinine has met with little favor even in the intermittent forms, and, indeed, I have seen an exacerbation of symptoms following its use. The coal tar products alone or with opium have appealed to some, probably on account of their analgesic and antifebrile effects; but in their administration the blood changes, the weakened organs, especially the heart, and the prolonged course of the disease must be considered. Aconite has been unwarrantably condemned. Given after the homeopathic method, small doses frequently repeated, and later alternated with belladonna, it reduces the fever and allays restlessness with no untoward after effects. Tincture of belladonna itself has been favorably considered in this disease, probably because of its sedative effect upon the peripheral nerves, and possibly of its control of the secretions.

Some advocate stimulation from the beginning. However, it is better practice to withhold this until it is demanded by the circulation or the onset of a chill. In this disease, as in pneumonia, strichnine is preferable to alcohol, and there are times when nitroglycerin, ammonia, camphor, or musk is preferable to either. I have no authority of writers or experience, but indications favor the frequent administration of hot decinormal salt solution as a means of stimulation, and of effecting improvement in the amount and quality of the circulating fluids as well as for washing out the morbid products through the kidneys.

The use of ether and choloroform has met disapproval, but in case of prolonged convulsions, I should not hesitate to employ them freely.

If through paralysis or extreme opisthotonos the muscles of the throat become useless so that food

and medicine cannot be swallowed, the end is not necessarily fatal. The uses and limits of rectal feeding are well known. Another method that may be of value is the forced feeding frequently employed with the insane. A soft rubber catheter of suitable size, attached to a fountain syringe, is introduced into the stomach through the mouth or one nostril by means of which liquid food is passed. I recently kept a child of fifteen months old alive over two weeks by this method, it finally recovering.

On account of the extreme hyperesthesia, little can be done with paralytic conditions until the disease has abated. Convalesence may then be hastened and the persistent paralysis overcome by electricity and massage, in which camphorated oil will be of assistance to relieve soreness. The nourishment should be gradually increased in solidity and quantity. Olive or codliver oil by innuction, tonics and digestants, with or without the mineral acids, may be given as in the prolonged convalesence of other diseases.

One thing more to be impressed forcibly upon those in attendance upon patients with cerebrospinal meninigitis is that no matter how unfavorable the symptoms, or how near to death the patient, the case must not be abandoned until death has actually occurred, as a greater number of apparently hopeless cases have made a perfect recovery in this than perhaps in any other acute disease.

Summary.—Cerebrospinal meningitis when first recognized was purely epidemic in character, and is now endemic in large cities. Its method of transmission from place to place and person to person is unknown.

According to the latest and best investigators, the exciting cause of the epidemic form is the diplococcus intracellularis meningitidis. And no evidence has been produced to prove that the cause of epidemic and sporadic cases is not the same.

The probable entrance of the pathogenic germ into the system is through the respiratory tract, especially that portion covered by the Schneiderian membrane. And its point of attack and usual seat of greatest activity is the base of the brain, from which it involves other portions of the meninges of the brain and spinal cord.

Its action is that of a septic invasion, and its symptoms a combination of toxine poisoning, nerve irritation and pressure.

The rate of mortality in late epidemics has been about 50 per cent., which may be lowered by a better agreement among the profession regarding methods of care and treatment.

Spinal puncture is a requisite of exact diagnosis, but as a method of treatment it is still in the experimental stage and leaves much to be desired.

Old methods of treatment may be made effective and reliable if used with decision and pushed to the limit of therapeutic effect.

Cerebrospinal meningitis in its worst form is amenable to treatment.

Frost Building.

RECENT STUDIES IN THE DIAGNOSIS OF RABIES.*

By DANIEL W. POOR, M.D.,
NEW YORK.
ASSISTANT BACTERIOLOGIST, RESEARCH LABORATORY OF THE BOARD OF HEALTH.

It is obvious to those who have to deal with people bitten by animals supposedly rabid, that a quick method for the diagnosis of this disease in the animal is most desirable. The length of time consumed by the inoculation test, with its consequent suspense and worry to the patient, together with the resulting delay in starting treatment, and further the occasional failure of the test through premature death of the animals from septicemia, are all reasons for stimulating work on the histological methods of diagnosis.

Since the time of Pasteur, much work has been done along this line, and it may be of some interest to summarize very briefly the results without going extensively into the technicalities of the subject. It is obvious that a satisfactory method of diagnosis must fulfil, as nearly as possible, the following conditions. First, the lesions should be characteristic of the disease; second, they should appear early in the disease as well as late; third, the technique should not be so difficult and exacting as to render its accomplishment frequently impossible under the conditions which we have to meet practically, and further, the lesions should be sufficiently definite to form the basis of a positive opinion. Lastly, it is desirable that the microscopical picture be as little as possible affected by the changes produced by postmortem decomposition and freezing.

Some years ago Babes described lesions which he considered characteristic of rabies, the essential points of which were, a collection of embryonal cells surrounding the central canal of the cord, and the ganglion cells, particularly in the medulla. The ganglion cells degenerate—chromatolysis being especially characteristic—and their spaces are occupied by the embryonal cells which constitute the so-called "rabic tubercle." From what can be learned, this method has not been in general use extensively, owing to the fact that these lesions are not constantly present in rabies, and that they may also be found in other conditions.

Later, Van Gehuchten and Nelis described changes in the sympathetic ganglia, the intervertebral ganglia, and in the plexiform ganglia of the pneumogastric nerve. In these locations the nerve cells lie in capsules lined with endothelial cells. The changes said to be characteristic of rabies are the atrophy and destruction of the nerve cells brought about by the new formed cells from the capsule, which finally occupy the entire capsule.

Ravanel, who has used this method of diagnosis, considered that the changes in the intervertebral

* Read before the New York Academy of Medicine (Section on Medicine), March 21, 1905.

ganglia are more constant than those in the medulla. He has reported a series of twenty-eight cases, including eleven dogs, one cow, and one horse, all having street rabies, and fifteen rabbits inoculated from these animals. In all except the horse positive changes were found, although in one of the cases they were very slight. In twenty-one cases examined for the lesions described by Babes, seventeen showed characteristic lesions. In two only chromatolysis of the cells was found, and in two no lesions were seen. Similar lesions to those of Van Gehuchten have been found in the ganglia by Crocq in one case, and by Van Gehuchten in three cases of diphtheria. Four cases in man have been reported as having lesions identical with those of rabies, including epithelioma of the Gasserian ganglion, acute ascending paralysis of the cord, and carcinoma of the rectum. It is also stated that the lesions of Van Gehuchten and Nelis are not well marked in the early stages of the disease. It seems, then, that the rabic tubercles of Babes, while frequently found, are not constant. The various phases of cell degeneration, such as chromatolysis, granular degeneration, loss of nerve processes, and the various stages of cell destruction are interesting to observe in connection with the pathology of the disease, but they can scarcely be made the basis of diagnosis, since they may be caused by other poisons. Further, owing to the great susceptibility of the nervous system to rapidly undergo post-mortem change, together with the frequent production in it of artefacts from rough handling and improper fixatives, we have still further reasons for considering these minute changes as unreliable for diagnosis under the conditions which we have to meet practically.

Assuming that the lesions of Van Gehuchten are more constantly found in rabies, the great difficulty of the dissection of the intervertebral and plexiform ganglia makes this method undesirable, to my mind, as a routine method of diagnosis.

More recently, in 1903, Negri of the University of Pavia, has made important observations on the pathology of rabies, describing minute bodies, since called Negri bodies, or corpuscles, which are found chiefly as cell inclusions in the Purkinje cells of the cerebellum and in the large ganglion cells in the region of ammons horn. Negri and some others believe these bodies to be the causative factor in the disease, and classify them among the protozoa. While not attracting much attention at first, these capsules have been studied and reported on latterly by a large number of observers, and they have become the basis for a method of diagnosis in a number of laboratories. Briefly described, these bodies may be said to be minute structures, varying in size from one to twenty-three microns in diameter. The shape is round or oval, but may be quite irregular. The staining reaction is eosinophile. In structure they may be homogeneous, ring formed, or vacuolated. They may contain irregularly grouped granules, or they may present a certain definite structure, namely, that of a mass of protoplasm containing one or more nuclear-like bodies surrounded by circular unstained areas. This structure has also been demonstrated by Dr. Williams of the Research Laboratory in stained smear preparations. They have been seen in the hanging drop as well as in stained preparation. They are said to preserve their form in spite of putrefaction of the brain, after prolonged immersion in glycerin, and after several days' drying. From personal experience, I can state that they may be found after such marked post-mortem change has occurred as to render the nerve cells themselves unfit for the histological study of their own structure. Further, I have found them easily in a brain packed in ice for forty-eight hours and which had become completely frozen. These bodies are not found in the salivary glands.

As to the nature of these cell inclusions, suffice it to say that, while some believe them to be protozoa, others hold that they represent the degeneration of red blood cells, or of some of the cellular elements of the central nervous system. The following series will give an idea as to the frequency with which these bodies have been found. Taking the combined statistics of six European laboratories, we have a total of 550 observations. In 344 cases the lesions described by Negri were found. In every one of these cases the animal was proved to have rabies by the biological test. In 206 cases the lesions were not found. Out of this number, eleven cases were proved by inoculation to have had rabies. From these figures one may conclude that the finding of these lesions is practically conclusive evidence of the existence of rabies, and that in the failure to find them we have a possibility of error of about 5 per cent.

In investigating this subject at the Health Department laboratory, we have made use of material from the following sources, viz., 21 dogs, 24 guinea pigs, 10 rabbits, 3 horses, and 4 human cases. These figures represent the total number of cases of proved rabies as well as control cases. Of this number, there were 17 cases of rabies occurring naturally, *i.e.* from the bites of animals proved rabid. In 16 cases the disease was produced artificially in dogs, guinea pigs, and rabbits, and 22 cases were used as controls. Of the 16 cases occurring naturally, 13 were dogs, 2 horses, and one a human case. All these cases showed the Negri bodies, the diagnosis being easily made by the microscopical method. By that I mean that after a search of about ten minutes at most of a single section of a small piece of either the cerebellum or ammons horn, or both, the diagnosis was made. In most of the cases a much shorter length of time was sufficient. In one of the experimental dogs the disease was produced by the inoculation of street virus in the region of a peripheral nerve, so that the condition would simulate that occurring naturally. This animal was allowed to go nearly to the time of death before being killed. The Negri bodies were found to be very numerous in the brain. Another dog similarly inoculated was killed on the day he showed the first symptoms of nervousness. A careful examination of a section of both cerebellum and cerebrum failed to show the lesions, though it is possible that an examination of a number of sections might have revealed them. That the case was examined very early in the disease is shown by the fact that the submaxillary glands had not yet become infectious. By mistake, a portion of the brain tissue was not saved for inoculation. It may be said here that the majority of the dogs sent to the laboratory were killed during the course of the disease, some of them after only a day's sickness, yet the lesions were sufficiently pronounced to make the diagnosis easy.

In the rabbits and the guinea pigs the disease was produced by the subdural inoculation of the virus. All of these cases showed the lesions, but it is hardly fair to consider these cases as having equal importance with the others in estimating the diagnostic value of the method, inasmuch as it appears that there is a relation between the number of these bodies present in the brain and the proximity of the site of inoculation to the brain.

The control material was taken from the following sources: Five normal animals, three dogs suffering from unknown conditions, which were killed on

suspicion of having rabies, but proven by animal inoculation not to have had the disease. In addition there were five cases of experimental diphtheria in guinea pigs, a case of staphylococcus infection including involvement of the brain in a rabbit, a case of general pneumococcus infection in man, one of traumatic cerebral hemorrhage in the human subject, and also one case of human tetanus and six cases of experimental tetanus in guinea pigs. In none of these cases was anything resembling Negri's corpuscles found, except in one of the cases of experimental tetanus. In this case there were a few minute eosinophile bodies occurring as inclusions in the Purkinje cells of the cerebellum. They showed no internal structure, and did not look exactly like even the structureless bodies found in rabies, and it is my feeling that one familiar with the appearance of these inclusions would not mistake them in making a diagnosis. However, it must be admitted that the similarity is sufficiently marked to be suggestive as to the nature of these cell inclusions. These diseases resemble each other in that in both the virus travels by the central nervous system. We may suppose that all these inclusions—those showing the regular definite structure seen in rabies, together with the structureless forms seen both in rabies and occasionally in tetanus, are one and the same thing. In this case, of course, it must be assumed that they are all degeneration forms. Or it may be supposed that the structured forms found in rabies alone are the causative factor in this disease, while the other forms are the result of a person acting especially on the nervous tissue and causing degeneration of its elements. So far as I know, the study of the morphology of these bodies has not progressed sufficiently far to throw light on this subject. However, as we are considering the diagnostic value of these lesions, it is to be noted, first, that even assuming their appearance identical in the two diseases, they are very commonly found in rabies, and are probably but rarely present in tetanus. Further, the dog, which is the animal most commonly afflicted with rabies, but rarely contracts tetanus. It would seem that much more extensive observation should be made on the histology of tetanus to clear up these points.

Even assuming that these lesions be definitely proven to be degenerations of the central nervous system, it seems quite possible that, when occurring in the numbers in which they do in rabies, they may still prove to be of great diagnostic value, since we must admit that, owing to the peculiar manner of transmission of the virus and the very long period of incubation and other peculiar features, this disease occupies a very unique position, and its pathology may be correspondingly unique.

With regard to the technique of the examination, one will find it necessary to take a small portion of the brain from both the cortex of the cerebellum and from the Ammon's horn, as the bodies are sometimes numerous in one region and not in the other. The tissue may be fixed in Zenker's fluid and stained with an eosin-methylene blue combination, in which case the inclusions stand out very clearly as red structures in the blue background of the cell body. Or absolute alcohol may be used as a fixative and hematoxylin and eosin as the stains. In this way a diagnosis may be made within twenty-four hours. The paraffin method of imbedding is to be preferred.

In conclusion, then, it would seem that in this method we have the means of making a rapid diagnosis, which is of about the same grade of accuracy as that laboratory diagnosis of tuberculosis or diphtheria. That, further, the lesions are, as a rule, found early in the disease, and are not affected by changes in the brain tissue incident to the delay of shipping the material to the laboratory from a distance.

Further, the material for examination is easily obtained, and may be collected by any competent veterinarian and sent in the fixing reagent to the laboratory, thus saving time.

While further work on control diseases should be done to establish fully the standing of the method of Negri, it seems fair to conclude, from what has thus far been done, that we have in it a means of accomplishing what has long been sought, namely, a rapid diagnosis of rabies.

MODERN METHODS OF TREATMENT IN OBSTETRICS AND GYNECOLOGY.*

By J. A. SCHMITT, M.D.
NEW YORK.

Physicians and medical congresses which make obstetrics and gynecology their special study have of late devoted much time and labor to the treatment of diseases which are also of great interest to the general practitioner. He is first called upon to test the value of measures recommended, and is frequently placed in a position to submit practical suggestions. Puerperal fever, for example, belongs to this category. It has been banished from the hospitals to the home of the parturient woman, where the physician has to lend his first aid. Though puerperal fever has the lowest mortality of all the infectious diseases, still better results could be obtained by a more thorough education and stricter control of the midwives, to whom most confinements are entrusted. They can carry the infection from patient to patient without being in any way held responsible. It is, however, not the prophylaxis, but the modern treatment of puerperal fever to which I desire to call your attention. Let us suppose that on the third day after parturition the patient is attacked by chills and fever. As is frequently the case, we are unable to find any localized inflammatory lesion.

Nevertheless, it is advisable that the treatment should be guided by the idea that only two pathological processes can underlie this morbid condition: Retention of decomposed secundines, or streptococcus infection of the placental site. Against both we direct our therapeutic measures. Curettage has found favor with many physicians. It is employed for the removal of placental residues, blood clots, and for scraping away infected areas of the endometrium. For the former indication, the use of a dull curette may be excusable, although the digital removal of retained secundines is by far to be preferred. The latter indication is based on the false premises that we can effectually master the infection by scraping away the diseased area. This, however, is not the case; we merely create new injuries and open new channels of absorption, thus assisting in spreading the local infection. We cannot even check the septic inflammatory process in an external wound by scraping away the diseased tissues, unless we follow this procedure by the efficient and continuous application of antiseptic dressings. As a matter of course, intrauterine irrigations are to be recommended; but we must not expect more than a simple cleansing of the uterine cavity. Digital removal of the abnormal uterine contents, combined with uterine irrigations, are not the only means at our command. The more serious streptococcus infection calls for the immediate injection of streptococcus antitoxin. While the older reports concern-

*Inaugural address of the president of the German Medical Society of the City of New York.

ing injections of streptococcus antitoxin in puerperal septicemia were conflicting and frequently unfavorable, the results lately obtained are far more promising. It was to be expected at the outset that streptococcus antitoxin would not neutralize the toxins in puerperal fever, caused by other varieties of germs, as staphylococcus, bacillus coli, and gonococcus, but even in pure streptococcus infection the results derived from injections of streptococcus antitoxin were at first far behind expectations. This has completely changed since we have begun to employ larger doses (up to 100 c.c. for an injection) of a modified antitoxin obtained by inoculating the horse directly from puerperal parturients. The favorable results reported from hospitals in which such a modified antitoxin in large doses had been used are surprising. Desperate and seemingly hopeless cases in which the blood revealed pure cultures of streptococcus recovered completely. As the serum which was heretofore employed was exclusively derived from the blood of small animals and administered in small doses, the therapeutic failures could readily be explained. It is therefore necessary, in order to obtain both favorable and uniform results, to insist upon the employment of an antitoxin which has been prepared in the way indicated above. Furthermore, it should be delivered in vials containing at least 50 c.c. It is advisable to inject 50 c.c. of the antitoxin as early as possible, even if the bacteriological examination of the blood and the lochia has not been concluded. The injection has to be repeated within twelve to twenty-four hours, the treatment to be guided by the observation of the pulse and temperature. Even prophylactic injections have been recommended in cases of protracted parturition. We have still other means at our disposal which are intended to remove the toxins from the blood, or at least to dilute them. I refer to the injection of physiological salt solutions with or without previous venesection. These are undertaken with the view to wash out, as it were, the circulatory system, and at the same time to incite the different organs, and especially the glands and kidneys, to renewed activity. Their use is not limited to the treatment of puerperal fever, but is indicated in all forms of sepsis in which we assume the presence of bacteria or toxins in the blood. The salt solutions can be introduced intravenously, subcutaneously, or per rectum. The first method is the most efficient, and the last the least reliable. By combining the one or the other of these methods with the above-described treatment, we fulfill all requirements which the modern treatment of puerperal septicemia calls for. In desperate cases the removal of the uterus and appendages has been advised; but the infection of the system has generally so far advanced, and the vitality of the patient has been so much lowered, as to minimize the success of surgical interference.

The treatment of eclampsia has of late received considerable attention from obstetricians. The knowledge of the causative factors of a disease naturally renders therapeutic interference easier. It may therefore be profitble to premise the more essential points of the etiology of eclampsia. Eclampsia is caused by poisonous material circulating in the blood. The poison is not uniform, and in most cases its production is attributable to a nephritis which causes retention of urinary constituents. Compression of the ureter may also lead to pathological changes in the kidneys and subsequent retention of urinary elements. Instances in which we cannot demonstrate pathological processes in the kidneys lead us to suspect other organs, as the intestines or the liver, the placenta or the fetus as a source of the poisonous material. Lately the view that the placenta and fetus originate the deleterious substances while the changes in the kidneys, liver, etc., are only secondary has been advanced by some and denied by many others. The poisons produced in these organs need not necessarily be the same as those due to retention of urine. Their action, however, gives rise to the same clinical symptoms. These poisons possess the power of decomposing the blood and producing capillary thrombosis and hemorrhage, necrotic foci in the liver, areas of softening in the brain and heart, degenerative changes in the convoluted tubules of the kidneys, etc. While these poisons do not produce convulsions under ordinary conditions, they easily lead to convulsions in the pregnant woman, because the organism of the latter shows a predisposition to convulsions, just as does that of the child, on account of a greater irritability of the nervous system. In the treatment of eclampsia we find many therapeutic measures which, having been found useful, are still warmly recommended. Amongst these I may mention the hypodermic injection of morphine, chloral enemata, chloroform narcosis, sweating by the hot pack, and venesection, to which is to be added saline transfusion. Lately thyroid extract has also been highly spoken of, on the theory that the thyroid secretion and the production of antitoxic substances furnished by the gland are deficient. Obstetricians are almost unanimous in recommending the immediate evacuation of the uterus, in order to check the convulsions. If labor has begun and the cervix is soft and yielding, then rapid dilatation is easily accomplished.

If, on the other hand, labor pains are absent, the cervix hard and unyielding, then the ordinary methods do not accomplish dilatation in a sufficiently short time. Besides, they may give rise to lacerations and contusions of the cervical tissue, that render the subsequent healing process more unfavorable than a clean incision. The incision into the lower segment of the uterus, also called vaginal cesarean section, is made as follows: The bladder is separated up to the peritoneal fold as in vaginal hysterectomy, and the womb opened by a vertical incision through the anterior wall, as far as it has been uncovered. The fetus is then extracted, and the uterine wound closed by sutures. Although in skilled hands a sufficient dilatation of the cervix can be effected by other means, the uterine incision must be accepted as a valuable addition to obstetric operations. It makes speedy delivery possible in a short time, and is indeed the modern accouchement force which fulfills three indications at the same time, viz., narcosis, venesection, and a rapid evacuation of the uterus.

There are cases, however, in which even after the uterus has been emptied the convulsions continue, and at the same time the albuminuria, with diminished secretions of urine approaching anuria persists. It had been observed, in cases of suppression of the urine in scarlet fever and multiple abscesses of the kidney, that an incision or splitting of the kidney had re-established the urinary flow, and saved the patient's life. In whatever way we may explain the favorable influence of the renal incision or decapsulation on the function of the kidney—the majority lean towards the view that as a result of the surgical procedure, excessive intrarenal pressure from congestion is diminished—the re-establishment of renal function, and therefore the propriety of the operation in puerperal eclampsia cannot be denied. But we should not forget that this operation is undertaken for the relief of anuria and its possible fatal consequences, and not for the cure of Bright's dis-

ease. Those of you who are interested in symphyseotomy, and have performed it in private practice, are not surprised at the sober judgment that has replaced the original enthusiasm over the brilliant idea of the artificial widening of the pelvis. Even in hospitals, with a sufficient number of assistants and with asepsis carried out with the minutest details, disagreeable complications, as excessive hemorrhage, injury to the bladder and urethra, and, above all, infection by the lochia, cannot be prevented. The practitioner at the house of the patient needs a simpler and less dangerous operation. These requirements seem to be fulfilled by Gigli's operation, which can be performed very rapidly and with very simple instruments.

An incision about two centimeters in length is made external to the spine of the pubes, direct to the bone. The soft parts are now separated with the finger from the posterior surface of the pubes, down to about where the descending and ascending rami meet. A uterine sound—some prefer a specially curved Dechamp's needle—is now passed through this channel, under the lower border of the ramus of the pubes through the tissues of the labium majus, until it reaches the skin, which is then incised. To the head of the sound Gigli's chain saw is fastened by a thread and drawn up through the wound. The bone can now be sawn through, subcutaneously. It is advisable that the lower opening should be more external than the upper, so that the section of the bone slants from above downwards and outwards, thus placing more tissue, as a protecting pad, between the ramus and the vaginal wall. The danger of lacerating the vagina and creating a communication of the wound with the lochial discharge is thus avoided. By the separation of the bone, the conjugate vera is increased about three centimeters, so that the lowest limit at which Gigli's operation is justifiable is a conjugate of seven centimeters, and, in a generally contracted pelvis, about eight centimeters.

It is hardly necessary to call your attention to the important changes in the treatment of contracted pelvis that have been brought about by this artificial widening of the pelvis. Now the obstetrician has an easy and not dangerous operation at his command, so that in cases of contracted pelvis he can wait until full term and deliver the woman of a living child, while formerly, even with the induction of premature labor, frequently enough all his efforts were frustrated by the delivery of a non-viable child. Moreover, it relieves us of the gruesome work of perforating the skull of a living child, an operation unworthy of an advanced stage of science.

In gynecology the operative treatment of uterine cancer has of late undergone a great change. Following upon the favorable results obtained by the complete extirpation of the glands, muscles and connective tissue in carcinoma of the breast, a similar method has been devised for the treatment of uterine cancer by the radical removal of the surrounding tissues within the pelvic cavity, through an abdominal incision. The vaginal route offers but a limited space and makes it impossible to remove the diseased tissues at a great distance from the uterus. The indications for operation could therefore not be much extended. The abdominal method, on the other hand, gives us a better view of the field of operation, and permits us to remove diseased tissues which could not be reached by the vaginal route. The operation as practiced at present is, in short, as follows: After opening the abdominal cavity in Trendelenburg's position, the ureter is laid bare, the infundibulo-pelvic and round ligaments are ligated and cut through, the bladder is separated, and the uterine artery tied; next the recto-uterine ligaments are separated from the rectum and the pelvic wall, the parametric tissue is dissected out to the pelvic wall, and the upper part of the vaginal canal laid bare in its entire circumference. This part of the vagina is now ligated below the vaginal portion with strong silk thread; to prevent the escape of cancerous material while the vagina is severed and the uterus taken out of the abdominal cavity. The iliac vessels are now uncovered in order to remove enlarged glands which are principally situated on the inner and outer sides of the vessels, and also in the triangle between the internal and external iliac vessels. The abdominal cavity is then closed by suturing the peritoneum of the bladder to that of the posterior pelvic wall. That this operation cannot compare in thoroughness with amputation of the breast is obvious. The numerous lymph vessels and glands and their widespread ramifications render complete removal impossible.

We must therefore be content with the removal of the visibly enlarged glands; but even this is an advantage which is still further enhanced by the possibility of the removal of the parametric tissue, the recto-uterine ligaments, which often contain carcinomatous material, and a large part of the vaginal wall. The advantages thus gained place us in a position to operate in cases which formerly were considered inoperable; furthermore, the chances of relapse are thus considerably decreased. We must not, however, lose sight of the shortcomings of the abdominal method. It is a serious and protracted operation, which has a large primary mortality. It does not give complete satisfaction, because we can remove only the microscopically changed glands, and it easily leads to necrosis of the ureter and fistula caused by the denudation and long exposure of the ureter. This last drawback is probably the most serious and the most liable to discredit the operation. Still I believe that the danger of necrosis and fistula of the ureter can be avoided if in isolating the ureter we preserve a protecting sheath of connective tissue. But even with this improved operation for uterine cancer there remain a considerable number of inoperable cases. The question therefore arises whether it may not be possible in some way or other to bring the early stages of uterine cancer to the cognizance of the patient. In Germany an attempt has been made to teach women the first signs of uterine cancer, by printed circulars. This well-meant plan will, I am afraid, fail, since the initial symptoms are so little characteristic that the majority of women will hardly consider them worthy of notice, still less worthy of treatment. We have no pathognomonic symptoms for beginning uterine carcinoma. Suspicion is generally aroused in older women who, having passed the menopause, after a time begin to bleed anew. In younger women, with irregular menstruation and discharge, the initial signs are passed over in a large number of cases even by the physician, especially in incipient cancer of the endometrium. Those patients are less unfortunate in whom the carcinoma takes its origin in the vaginal portion; we can see and feel it there. I expect far better results from an appeal to the practitioner, who should consider all cases of menorrhagia, metrorrhagia, and of blood-stained discharge, as suspicious of cancer, and should differentiate this disease from those diseases that produce the same symptoms. Digital exploration of the uterine cavity, and microscopic examination of scrapings of the mucous membrane are the only reliable diagnostic aids.

132 East Seventy-third Street.

SOME POINTS OF VIEW IN REGARD TO THE TIME WHEN TO PERFORM MYRINGOTOMY AND THE MASTOID OPERATION.*

By EMIL AMBERG, M.D.,
DETROIT, MICHIGAN.

It is reported that De Gravers was the first who incised the drum membrane in the living subject. Astley Cooper, according to Schwartze, was not acquainted with this fact and he perforated, with happy result, in the years 1800 and 1801, the drum membranes of three people who were hard of hearing, and of a very deaf person. This method was later abandoned. Myringotomy was reintroduced by Schwartze on the basis of exact indications. Of practical importance is the opposition recently raised against the incision of the drum membrane in acute suppuration of the middle ear.

Zaufal and Piffl claimed that in most cases of acute middle ear inflammation myringotomy was not necessary. Buerkner[1], intended to test these claims, and chose fifty cases for trial, but he had not the heart to continue after he had watched forty-four cases. After a careful observation he came to the conclusion that patients on whom myringotomy was done early got well sooner than those on whom it was not done. On the fifth day 49.5 per cent. of the incised cases were well; of those which perforated spontaneously only 5.4 per cent.; within the first twenty days the relation was 90.5 per cent. to 43.4 per cent. Functional disturbances in incised cases occurred in 3 per cent.; in spontaneously perforated cases in 12 per cent. Recurrences occurred in 8.5 per cent. of incised cases and in 20.7 per cent. of spontaneously perforated cases. Complications on the part of the mastoid process resulted in incised cases in 1 per cent.; in spontaneously perforated cases in 7.4 per cent. In all incised cases the opening closed; in 14 of the non-incised cases the opening remained even after the discharge stopped. Buerkner comes to the conclusion: "I therefore cannot find any reason to abandon the practice followed since more than twenty-five years, to create as soon as possible a passage for the exudate by incision of the drum membrane in all cases of otitis media in which there are present violent pain, considerable fever, and partial or complete bulging of the reddened drum membrane."

Jansen[2] of Berlin, says that we never do any damage by myringotomy, but frequently do a great deal of good, provided it is performed with all precautions.

Koerner of Rostock[3], says that there does not exist any excuse for not performing the paracentesis when the drum membrane is bulging and when fever and pain are present.

Heiman, Jr.,[4] speaking of the palliative treatment of acute middle ear inflammation, says: "In none of the cases in which the drum membrane was incised were there any complications, whereas of the cases with acute suppuration, in which the drum membrane was not incised, two took an unfavorable course and had to be operated upon for mastoiditis, and six others became chronic."

Kretschmann[5] of Magdeburg, cites a case in which death resulted from meningitis. Against his advice, the patient had caused a retention of pus by blowing a large quantity of boric acid powder into the external auditory canal. We can consider a retention caused by a thickened drum membrane in a similar light.

The question when to interfere surgically in mastoiditis agitates the otologists at the present time as much as does the general surgeon the similar question in cases of appendicitis. It appears to the writer that a fixed rule cannot be established for all cases, because so many factors must be considered which cannot be estimated correctly. The power of resistance of the tissues, the character of the microbes, their virulence and ability to produce toxins cannot be measured by the aid of the thermometer nor by that of the watch. Also the variations in the anatomical configuration of the mastoid process cannot be determined with certainty from the outside. A few views may be mentioned.

Dench[6] reported that a pneumococcus mastoiditis gives a relative favorable prognosis. Schulze of Halle does not agree with Dench, and he also does not believe in the necessity for interference already after forty-eight hours, as proposed by Dench. He admits for a streptococcus infection an early coaffection of the bone, but he does not agree with those who will not wait longer than forty-eight hours before opening the mastoid.

At the Seventh International Otological Congress at Bordeaux, Heiman[7] of Warsaw, speaking of the indications for opening the mastoid process in cases of acute middle-ear suppuration, recommended the immediate opening of the mastoid process when there exist signs of meningeal irritation which are not caused by retention of pus and after broad opening of the tympanic cavity. This statement, of course, invites the question whether it is not safer to prevent the possibility of symptoms of meningeal irritation by an early opening.

Schulze[8] of Halle says: "The presence of pus in the mastoid process is always an indication for surgical interference."

Fiske[9] of Chicago speaks of a case of a 58 year old man suffering for three days from suppuration in the ear. The pain decreased the third day after spontaneous rupture of the drum membrane. A physician insufflated boric acid powder, and the patient became worse on the fourth day and died on the fifth day of meningitis, which diagnosis was confirmed by autopsy.

I had recently under my observation a case, to which I was called on the second day after the manifestation of an infection. I performed a myringotomy, and two days later I opened the mastoid, finding practically the whole bone gray and also free pus in the bone. The symptoms were very severe. The patient recovered. To the patient's knowledge, the whole active process up to the time of operation had lasted four nights and three and a half days.

I have suggested for cases of this nature the name mastoiditis acutissima, dividing the types of acute mastoiditis into three groups: (1) Those which take a rapid course, clearly showing alarming local and general symptoms, especially of a toxemic character, and which do not respond to palliative measures. (2) Those which take a somewhat more protracted course, extending over a period of one or several weeks, exhibiting plain local symptoms, but which are not accompanied by intense pain nor by a grave affection of the whole system, and which, at least temporarily, respond to palliative measures. (3) Those which take a mild course.

The first type should be called mastoiditis acutissima; the second, mastoiditis acuta; the third, mastoiditis subacuta.

Grunert[10] recommends that in cases of mastoiditis the antrum should always be opened, because we are not yet so far advanced as to be able to exclude an antrum suppuration with certainty with our present means of diagnosis.

*Read before the Section on Surgery, Wayne County Medical Society, Detroit, January 23, 1905.

Schencke, in an article on "Endocranial Complications of Acute and Chronic Middle-Ear Suppuration,"[11] mentions that without a suppuration in the mastoid process, an inflammatory process can extend to the adjacent sinus wall, that it can penetrate the same and cause a thrombosis.

As important factors in determining the advisability of a mastoid operation, the condition of the patient must be taken into consideration, as mentioned before. In regard to the existence of diabetes, the following has been advanced:

Koerner[12] reports concerning the influence of operations on diabetes. He comes to the following conclusions: (1) In the light form of diabetes the operation can temporarily increase the excretion of sugar, without further detriment to the patient. (2) There seems not to exist a danger that the operation produces a grave form out of the light form. (3) Coma caused by the operation need be feared only when the diabetes showed before the operation the clinical appearance of the grave form, especially if the Gehardt test for acetoacetic acid in the urine is positive. (4) The light form of diabetes is not a contraindication against an otherwise indicated operation. (5) Operations which are vitally indicated may also be performed in the medium grave and in the grave form of diabetes."

Mueller,[13] in an article on "Neuroses and Mastoid Operations," speaks of the good influence of surgical interference on neuroses complicating ear affections, *e.g.* epilepsy, chorea minor, hystero epilepsy. Of his ten cases, nine patients are reported improved, one cured. In a boy with a middle-ear suppuration and chorea minor (operated upon in January, 1898), Mueller could report a complete cure also of his chorea (in 1902). He thinks the following points should be mentioned as essentially producing the good results: "(1) The narcosis and the surgical shock. (2) The loss of blood. (3) The influence of the after treatment, by which we mean the permanent drainage through the dressing."

In general, when deciding whether to operate or not to operate in a case of mastoiditis in which we have symptoms which even only point toward the necessity of surgical interference, we had better err to the safe side and open the mastoid. We can never come too early under any consideration, but we may in some cases miss the right time and be too late if we hesitate. An antrotomy in acute mastoiditis can be compared to a myringotomy in acute suppurative otitis media.

DECAPSULATION OF THE APPENDIX.

By A. E. ISAACS, M.D.,
NEW YORK.

ASSOCIATE PROFESSOR IN SURGERY, NEW YORK SCHOOL OF CLINICAL MEDICINE; SURGEON TO BETH ISRAEL HOSPITAL.

In the technique of appendectomy, difficulty is occasionally encountered, by reason of extensive adhesions of the appendix, due generally to the results of repeated previous attacks of local inflammation. These adhesions may be so dense that, to tear them would involve danger of tearing the adherent gut or of starting a hemorrhage difficult to control. Of course, with time and patience, these difficulties can generally be overcome, but both the length of time under anesthesia, and the amount of manipulation of the viscera bear so important a relation to the severity of post-operative shock and to the prognosis of the case, that anything that can limit one or both must be of the utmost importance in the technique of the operation.

These extensive and old adhesions are very troublesome when they involve a long appendix running down deep into the pelvis, or especially when it is turned upwards and towards the median line, under the ileum and its mesentery. To free such an appendix from its adhesions in the usual way, to locate and ligate its mesentery, and to control hemorrhage from torn adhesions at the bottom of a deep cavity, is hard work, and sometimes impossible within the length of time the patient's condition might permit.

Observing how easily the peritoneal coat could be peeled from the proximal portion of the appendix in the method, that I used for a time, of covering in the stripped and ligated stump with the peritoneal cuff, it occurred to me that the same principle could be utilized in dealing with the whole appendix when adherent, for the adhesions involve only the peritoneal capsule which there could be no harm in leaving in situ if the inner layers, the only offending part, were removed. Having tried this method in a number of instances where conditions called for it, and have found it of decided advantage, it has become an established procedure with me. It saves considerable time and trouble to the surgeon, shortens the operation and spares considerable handling and manipulation of the viscera. The method is especially useful in those cases of extensive adhesions where but a portion of the appendix can be located, be it either proximal or distal portion, and where the rest loses itself in the adhesions and cannot easily be traced. In such a case if the capsule of the available portion be split, and the pearly-white worm-like core raised from its bed, it can be followed in either direction without trouble and without fear of adhesions or bleeding and so removed in toto.

My method is as follows: having located some portion of the appendix, preferably the proximal, the capsule is incised longitudinally opposite the mesenteric attachment if possible, so as to avoid the larger blood-vessels. In this situation the hemorrhage is insignificant and hardly ever needs attention. The white, glistening surface of the middle layer is the guide to the depth of the incision. The incised serous coat peels off very easily, and with the blunt end of the scalpel handle or with a periosteum elevator, the core can be easily separated and raised from its bed without fear of hemorrhage. This white core now serves as a guide to the capsule, inside of which it can be loosened up a short distance, then the capsule split for that distance, and the procedure repeated till the whole length is delivered. When the appendix is perforated the inner layers are gangrenous and the core is, therefore, likely to tear within its capsule on the least traction. In such a case, while it makes conditions somewhat more difficult, it is comparatively easy to follow up the capsule, find the other end of the torn core and proceed with the decapsulation. There will frequently be found a point of maximum adhesions, centralized usually at the point of pressure-necrosis from a fecal concretion or due to some other cause, and when this is reached and freed by decapsulation, the remainder of the appendix, be it either the proximal or the distal portion, may be found comparatively free, and

can be dealt with in the usual manner, taking it off together with its capsule after ligation of the mesenteric attachment which, at this stage, can be easily recognized.

In a series of about one hundred appendectomies, statistics of which I will shortly publish, I had occasion to use the method in ten cases, but as I had not begun its use systematically till the series was about half over with, these ten cases can be considered roughly as the proportion of fifty where the method was useful. My recent experience tends to

Fig. 1.

The resected appendix in Case I. It shows very well the decapsulation from its proximal end to the point of perforation, where the concretion has been placed in situ on the specimen. Beyond the concretion is the gangrenous distal portion, thrown off by natural means, and its peritoneal capsule that was easy to separate as it was beyond the area of adhesions.

indicate that 20 per cent. is a moderate estimate of the general run of cases where the procedure may be of service.

As an illustration of the utility of the method under conditions frequently encountered, I will cite, with sufficient detail to bring out the main points, two recent cases where it has proven of great value:

Case I.—I. W., male, age 14, first seen by me November 13, 1904. Had been sick one week with abdominal pains, chills, fever, vomiting, etc., which symptoms were at first severe, but had become milder during the past two days. No history of previous attack. Temperature now 101½°, pulse 84, small and wiry, pain limited to left side of umbilicus, some dullness on percussion low down in pelvis and in left flank. Peritonitic facies and general poor appearance. Sent to hospital and operated on at once. Right oblique incision, general peritoneal cavity protected by gauze pads. Adhesions separated, very large abscess cavity encountered mostly to left of median line, and running down into the pelvis. With the pus was discharged a fecal concretion and the gangrenous inner coats of the end of the appendix. Cecum isolated and origin of the appendix located. Here it could be seen to turn up under the ileocecal junction where it lost itself in an apparently hopeless mass of adhesions, the various constituent parts of which it was impossible to recognize by reason of their inflamed, infiltrated and very adherent condition, and, therefore, not safe to try to separate. The serous coat of the available portion of the appendix, near the cecum, was incised, peeled from the core, and with a blunt instrument the latter was followed up and separated within its sheath, clipping the latter as the core was loosened. In this way the appendix was traced running between the ileum and its mesentery in front, and the posterior parieties behind, upwards and inwards to a point about opposite the umbilicus, from where the traction on the core suddenly pulled it out. This was seen not to be the end of the appendix, but was evidently the point of perforation through which the concretion escaped. The missing part beyond would be accounted for by the gangrenous end of the appendix mentioned above as having with the concretion been discharged with the pus. This was verified by following up the serous tube, which, beyond the perforation was comparatively free, and which was removed after the placing of a ligature, though it might have remained without any harm. The stump of the appendix was inverted and secured with a purse-string suture and the incision sewed up by layers except sufficient for drainage.

In this case I am confident that the boy's prompt and uneventful recovery, minus a diseased appendix to threaten him anew, was due to this procedure, for I can think of no other way in which that appendix could have been removed with reasonable regard for his chances of recovery from the operation.

Case II.—B. H., male, age 20, seen in consultation with Dr. N. Ratnoff, December 27, 1904. Had been under the doctor's observation only that day, but had been sick for five days, beginning with colic, pain right side, some vomiting, etc. No history of previous attack. Now no symptoms except local pain. Sent to hospital and operated next day. Gridiron incision. Deeper layers were edematous and on opening peritoneum quite an amount of free serous fluid was found. Infiltrated mass of gut and omentum adherent to parieties presented below incision, running downwards into pelvis. Lower portion of internal oblique and transversalis had to be incised to reach it. Protective gauze pads inserted and separation of adhesions begun. Appendix encountered in the mass, distended with fluid contents and black with gangrene, running deeply down into the pelvis from where it was released with some difficulty and the distal portion delivered. Towards the proximal end it was followed up as far as the cecum in the same way and freed by ligation of its mesentery. There were now about five inches in length of sacculated gangrenous appendix delivered, and here the difficulty began. While the proximal end was in contact with the cecum to its outer side, it did not seem to be the end of the appendix, and in the general mix-up of infiltrated and adherent

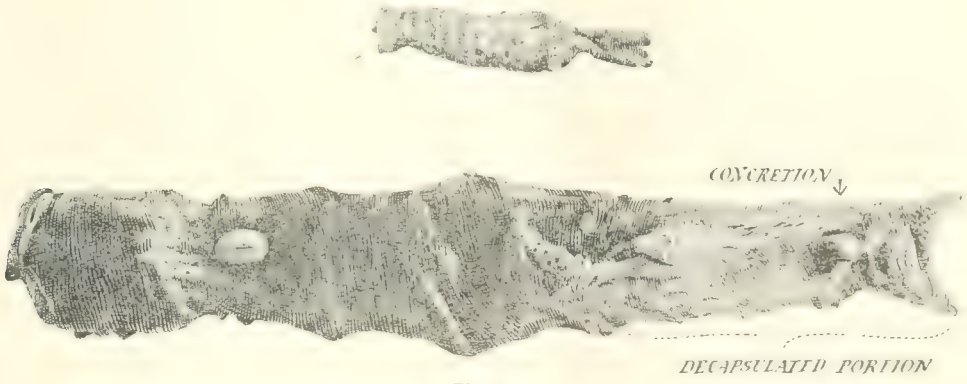

Fig. 2.

The large appendix in Case II. slit open and spread out and one of normal size, treated likewise, for comparison in size. The concretion responsible for the trouble is placed in its original position. Of the others only one is shown. The contrast between the decapsulated area and the portion with its capsule does not show so well because the whole structure was thinned out by distention.

gut, omentum, appendix and its mesentery it was difficult to decide whether the whole appendix was freed, or whether in spite of the five inches already out, there was more embedded in the mass. The latter looked likely, as the end of the gangrenous area had not been reached nor could the usual direct connection with the cecum be discerned. To tear the adhesions further would probably have burst the frail remains of the appendix, and have spilled its septic contents over the wound in which no pus had yet been encountered, and, furthermore, there was no guide as to where it would be safe to cut or tear. Under these conditions the serous coat was incised and separated on either side with the handle end of the scalpel until the core was raised from its bed. The separation was continued with a blunt instrument for about half an inch within the serous tube, this much of the tube clipped open and the procedure repeated. In this manner about two inches more of gangrenous appendix, running behind and to the inner side of the cecum, were delivered, followed by an additional inch of healthy appendix. The point between the latter and the gangrene was occupied by a concretion, of which there were three more in the distended portion, which acted as a ball-valve closing the appendicical outlet. Were it not for decapsulation, I doubt if it would have been possible to trace the appendix any further than its first contact with the cecum, and I would, in all probability, have been satisfied that it was all freed when five inches, ending up in the cecal wall, the appearance and relations of which were altered by inflammation and infiltration, were de-

Fig. 3.

An appendix removed in a case [illegible]; it was necessary to decapsulate about half its length.

livered, Even if it were positive that all were not out, the conditions would not have justified further attempts at enucleation by the usual methods. This was a case in which a most grave condition gave hardly any symptoms. Just previous to operation there was no more than local pain on disturbance of the parts. It was as angry looking an appendix as could possibly be, and certainly the largest I ever encountered. It measured 8½ inches in length, of which 8 inches were excised. Wound was closed except for a small gutta percha drain which was removed in 48 hours. Primary union.

For the excellent photographs I am indebted to Dr. I. S. Hirsch, Assoc. Radiographist of Beth Israel Hospital.

TUBERCULOUS TESTICLE AND THE X-RAY.

By W. B. DE GARMO, M.D.,

NEW YORK.

PROFESSOR OF SPECIAL SURGERY IN THE N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

I AM prompted to report the following case by reading the excellent article of Dr. J. B. Bissell (*Medical News*, July 16, 1904), entitled, "The Treatment of Tubercular Testicle." He says: "A palliative treatment, which seems to have great promise in it, is that held out by the use of the *x*-ray, radium, and the fluorescent solutions. In tuberculosis of the skin and glands the favorable results reported from this procedure promise much for the cure of tuberculosis of the testicle." Dr. Bissell does not, however, report any cases, nor have I seen cases reported by any writer as having been treated by the *x*-ray, and that is my apology for making the report of a single case. This case seems important, not only in (apparently) having been a pioneer case, but in the fact that the testicle on the opposite side had been previously removed and submitted to a well-known pathologist for examination, and in that fully two years have elapsed without recurrence of symptoms.

March 11, 1902. J. M., age 56 years, naturally a large and robust man, has always enjoyed the best of health. Admits gonorrheal infection twenty-five years previously, and thinks that at that time he had a swelling of one testicle, but is uncertain which one. No syphilitic infection. About five years since the left testicle began swelling, and with the increase of size there was gradually increased pain, never very severe, but enough to cause considerable discomfort. During the last eighteen months there has been a gradual loss of general weight, and on this account he has made an European trip and has taken treatment at various bath establishments abroad, without benefit. He did not associate loss of weight with the enlarged testicle, but believed that it came from some other unknown cause.

Examination showed the left testicle to be about the size of a large orange, hard, nodular, and tender to pressure. There was a small amount of fluid (about one ounce) in the tunica vaginalis, and this varied in quantity. A diagnosis of tuberculous testicle was made and its removal advised. This he would not consent to, and a local application of equal parts of tincture of iodine and fluid extract of belladonna was prescribed as a palliative measure.

Two months later, May 2, 1902, he returned, reporting diminished pain, but increase in the size of the testicle. Symptoms of the breaking down of the tissues were present, and operation was consented to.

On May 10 the testicle was removed and sent to Professor H. T. Brooks for examination, and in a few days he reported that it was "typical tuberculosis." The patient made a prompt recovery, and a decided increase in weight during the following two months.

At about this time, however, I discovered a pathological condition in the right testicle, and suspected at once its cause. I advised him to live out of doors as much as possible during the summer and await results. At the beginning of November he came to me with the testicle nearly as large as the one previously removed, but with the same, or even greater, repugnance against its removal.

The *x*-ray suggested itself to my mind, and I called up on the telephone three different friends who were using it extensively, but none had treated a case of tuberculous testicle. The patient gladly consented, however, to have Dr. F. B. Carpenter make a trial of it in his case, and the doctor's report is here incorporated. The patient experienced the most complete relief from pain at the very first application, and has not had to the present date any return of it.

"J. M. was referred to me by Dr. W. B. De Garmo on November 3, 1902, for *x*-ray treatment. There was a clear history of tuberculosis of the testicle, which was confirmed by the clinical appearance. The testicle was swollen to several times its normal size and was hard, painful, and quite tender on pressure. One hundred and twenty-six treatments of ten minutes each were given between Novemebr 3, 1902, and September 14, 1903. A medium tube was used at a distance of about ten inches. The first applica-

tion relieved the pain. The swelling and tenderness also gradually subsided until at the time of the last treatment the testicle was apparently of normal size and in normal condition."

Some recent writer, whose name I cannot now recall, has sounded a note of alarm regarding the use of the *x*-ray in the vicinity of the testicles, on account of it producing a probably subsequent sterility of the patient. Allowing the truth of this statement, it has little bearing on the treatment of these tuberculous cases, as in the majority of instances it is admitted by most authorities that if the case is of any duration, complete castration is the only safe procedure.

Epididymectomy may, undoubtedly will, check the pathological process if the case is seen and recognized in time. The onset and progress of the disease is insidious in the extreme, and the patient does not consult the physician in the majority of cases until it has left this, its usual, point of invasion and infected the body of the gland. The removal of the affected testicle may be followed by development of the process in its fellow.

Cumston ("Tuberculosis of the Testicle," *American Journal of the Medical Sciences,* July 9, 1904) justly holds that the radical treatment should not be allowed to become obsolete, and calls attention to the low mortality of castration. He strongly advocates eradicating the breeding point of the disease in this manner.

While my experience leads me to fully indorse these claims, I cannot lose sight of the possible ultimate results of castration in its effect upon the mind of the patient. The mortality is so slight in present-day surgery as to be scarcely taken into account, but castration must not be entered into without very serious consideration as to its subsequent effect on the patient, since its results may be disastrous. The patient should always know that it is done only as a life-saving resort, and even then his mental balance may be disturbed in contemplating his mutilation in later years.

If the *x*-ray will accomplish, even in a small number of cases what it has seemed to accomplish in the one just narrated, it is of extreme importance that all of those who are liable to meet with these cases should be quite familiar with the facts.

GRANULATION WOUND ADHESIONS, WITH A PRELIMINARY REPORT ON A NEW APPLICATION IN PREVENTIVE TREATMENT.*

By FREDERIC GRIFFITH, M.D.,

NEW YORK.

SURGEON, FELLOW OF THE ACADEMY OF MEDICINE.

In an article published two years ago (*Medical News,* September 27, 1905) I brought forward the theory that the healing of granulation wounds is dependent upon the mechanical principle of friction. The present contribution has in view the presentation of an application for preventive treatment.

The pathology of wounds is the pathology of inflammation which, with the complications arising therefrom, ranges the entire field of disease change. Inflammation being closely associated with both the pathological and reconstructive processes, it was impossible until the discovery of the factor of pus microorganisms to make a correct deduction of when the destructive gave way to the restorative function. To properly understand the healing of wounds of any sort it is necessary to notice particularly the rôle which inflammation plays in the reparative process. Formerly considered to be a disease distinct in itself, writers upon this subject, while differing in their explanations of some of the accompanying phenomena, are to-day generally agreed that inflammation represents a series of structural changes following the reaction of a part to an irritant. While the complete cycle occurs most often under the influence of microorganisms or their products, any form of irritation is sufficient to excite some of the phenomena. Wound healing, therefore, becomes a process of balancing between a mechanical change in the relationship of tissue texture or destruction of it and repair. Considered in this light, the process is simplified, and the principle, being the same for all forms of wounds, becomes one of mere adaptation.

Furthermore, while some investigators distinguish two kinds of wound healing, it can be shown that granulation is a mere excess of that which takes place after agglutination in a coapted, incised wound. When loss of substance requires that space should be filled up, as in badly contused and lacerated wounds, or where there has been loss of tissue and it has been impossible to obtain direct adhesion of the divided parts, and also in those which have become infected by microorganisms, healing by second intention or granulation formation takes place with phenomena somewhat as follows: Until the end of twenty-four hours the various tissues may be distinguished; later the outline is obscured by the gelatinous lymph and by a process of fatty degeneration, the blood coagulum being entirely replaced. About the third day the wound cleft is found to be made up almost entirely of round cells, some intermediate substance and the remains of the blood coagulum. Later come large epitheliod cells, being forerunners of granulation tissue formation and fibro-blasts which change into the fibers of the fibrillar connective tissue. Some of these newly formed cells become wandering cells, and regeneration within the new-formed tissue mass is likewise carried on by the fixed tissue cells. After the scar has become well formed a shrinkage in the newly formed connective tissue takes place with a consequent disappearance of a portion of the newly formed vessels; this causes the red color of the scar to blanch. From a consideration of that which has gone before it will be seen that it becomes a mere incident, depending wholly upon the nature of the wound whether more or less of the formative connective tissue is required to fill up the loss of substance following the injury. The granulation formation in an open wound is in nowise different from the vessel loop formation which takes place in a coapted, incised wound. According to some observers, two layers of granulation tissue are to be noted microscopically in a healing wound, the more superficial made up of vertical capillaries and the deeper containing a transverse meshwork of vessels from which the former originate, coming through a structure more or less dense according to age. Malposition, arising from excess of irritation of the ground network, giving rise to various pathological conditions such as keloid, cicatricial ulcer, pressure paralysis or neuritis (from nerve filaments becoming caught). The factor which above all else determines wound healing is the presence or absence of friction, or, taken in its broadest application, irritation. Whether it be due to mass motion of the wounded parts, or to the cellular destruction caused by pus germs, failure to secure perfect results will assuredly occur.

*Presented at a meeting of the Surgical Section of the New York Academy of Medicine, held October 7, 1904.

Friction during the progress of healing of a granulating wound surface is manifested by the outpouring of fluid. Profuse during the early constructive period, it becomes less as the granulation formation proceeds, until it ceases. The untoward reaction of the wound surface to irritation from motion, bacteria, applications or dressings is shown by fungoid formation upon the surface which slowly changes into coarse-grained, contracting scar-tissue.

For many years surgeons without apparent thought as to the causation have endeavored to meet outpouring fluid from wounds by an escape by drainage. The treatment of granulation wounds seems to be based more upon the individual whim of the surgeon than upon the well-founded principles which time has proven. That the early physicians clearly understood the frictional theory is demonstrated by their treatment of granulating wounds with balsams and oils, later by the addition of bulkier bases constituting salves, thus affording support for lubrication. The furtherance of healing is secured by dry wounds. Franciscus Arceus, who flourished in 1580, aware of the necessity for dry wounds, and writing at the time, says, "Wounds are not healed before they are dry, as writeth Hippocrates."

The value of a given application to a granulation wound will depend upon the amount of fluid which it causes to be produced. According to this principle dusting powders having in view the production of a scab mass are without exception irritating. Watery solutions, made directly or upon saturated cloths of gauze, fail of their purpose by the amount of relaxation and maceration which they cause. If an outer covering of sheet rubber tissue or oiled-silk protective be applied the condition is made worse by a direct bid for pus development being made. Heat of about the body temperature, moisture, and the presence of the germs are all three factors necessary for pus development upon a wound surface; the germs themselves are ever present, and to supply the other factors in the combination by this too common practice simply furthers infection, and the wound heals in spite of and not by the assistance of the dressing. Heat stimulation of granulating wounds by hot fomentation dressings are not considered in this connection.

An approach to the ideal application to an external granulating wound is the membranous quality rubber tissue when applied shingle fashion. This, however, is not an animal membrane, and therefore cannot react to the progressive changes of regeneration in the wounded tissues. The employment of the peritoneum of the ox known by the name of Cargile membrane marks, I believe, an epoch in the treatment of granulating wounds, and it is along the same general line that I would direct attention. The specimens of tissue membrane which I present consist of the gastrointestinal mesenteric attachments of the gray or sand shark *(Carcharias littoralis)* so common to the American coasts. Two or three square feet of this almost gossamer but tough membrane are obtainable from an ordinary sized fish. The specimens I secured are but sun dried, and give but a faint idea of the crystal film as it is found. A specimen kept some ten weeks in alcohol, which has no apparent effect upon the texture unless it is to increase the toughness, gives a better idea of the clearness. The ease in securing and cheapness of this material as a surgical application may be judged from a mere questioning of any of the professional fishermen, either beach men or deep-sea fishers, as to the numbers of otherwise worthless sharks which infest our coast.

East Sixty-fourth Street.

A Study of the Bone Marrow in Typhoid Fever and *Other Acute Infections*.—Warfield T. Longcope gives the following summary of his paper: The bone-marrow from twenty-six cases of typhoid fever showed certain definite and constant histological lesions. These lesions resembled very closely the changes in the mesenteric lymph nodes, lymphoid follicles of the intestine and spleen. The alterations were characterized by the presence of many lymphoid cells, large phagocytes, and foci of necrosis. There was more or less hyperplasia of the blood-forming cells. In many of the marrows from cases dying of perforation and general peritonitis there were, besides the disseminated foci of necrosis, diffuse degenerative changes in blood-forming cells, accompanied with marked edema and congestion of the tissues. Differential counts of the bone-marrow cells from ten cases showed a marked relative increase of the lymphoid cells over the granular myelocytes. The bone-marrow from fifteen cases of acute lobar pneumonia, four cases of peritonitis, one of acute cerebrospinal meningitis, one of retroperitoneal abscess, and one of puerperal septicemia, all showed the same variety of alterations, differing in many important points from the cases of typhoid fever. There was more or less extensive hyperplasia of the blood-forming cells, with a marked relative increase of the granular myelocytes over the lymphoid cells. In the cases of peritonitis due to causes other than typhoid perforation, diffuse degenerative changes were absent. In no cases of this group were foci of necrosis found. Large phagocytic cells were exceedingly rare or entirely absent. It is possible that the lesions in the bone-marrow in typhoid fever are in some way nearly related to and perhaps responsible for the hypoleucocytosis characteristic of the disease. It is also very probable that the lesions in the bone-marrow in acute lobal pneumonia, peritonitis, etc., are in close association with the hyperleucocytosis so often seen in these conditions.—*Bulletin of the Ayer Clinical Laboratory of the Pennsylvania Hospital.*

On the Influence of Copious Water Drinking.—P. B. Hawk concludes that copious water drinking causes an increased excretion of nitrogen and phosphorus by the urine. The increase in the amount of nitrogen eliminated is due primarily to the washing out of the tissues of the urea previously formed, but which has not been removed in the normal processes, and, secondarily, to a stimulation of photeid catabolism. The increase in the excretion of phosphorus is due to increased cellular activity and the accompanying catabolism of nucleins, lecithins, and other phosphorus-containing bodies. The course of the SO_3 excretion, while somewhat irregular, still showed a general tendency to run parallel with that of nitrogen. The course of the P_2O_5 excretion, as influenced by copious water drinking, was distinctly different from that of nitrogen or SO_3. In every instance the excretion of P_2O_5 was increased above the normal on each day of the water period, the maximum excretion occurring with absolute regularity on the second day of the increased water ingestion. There was a constant tendency for the largest percentage of the ingested fluid to be excreted by the urine on the days of copious water drinking.—*University of Pennsylvania Medical Bulletin.*

Effect of Tubercle Bacilli on the Growth of the Colon Bacillus.—Korczynski has found that the presence of tubercle toxin stimulates the growth of staphyloccocus, streptococcus, and colon cultures, these organisms growing much more actively in media containing toxins than in those that are pure. Streptococci and colon bacilli grow more actively the higher the percentage of tubercle toxins present. Tuberculin is more effective in this respect than tubercle bouillon. The toxicity of colon bacilli cultivated on tubercle media is higher than that of organisms grown under ordinary conditions. Tubercle and colon bacilli appear to be synergists, since animals succumb on receiving at the same time non-fatal doses each of colon and tubercle bouillon.—*Wiener klinische Wochenschrift.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, April 15, 1905.

THE TREATMENT OF PUERPERAL FEVER.

The Practitioner under its new management is continuing the practice initiated by its former editor, Mr. Malcolm Morris, of publishing at intervals special numbers. The issue for March treats of puerperal fever, all the papers being contributed by authorities on the subject. That dealing with treatment of puerperal sepsis is from the pen of Dr. Galabin, Consulting Obstetric Physician, Guy's Hospital. Local disinfection, he says, is the first question to be considered in the treatment of puerperal fever. For this purpose, a strong antiseptic such as a solution of mercuric iodide in alcohol, 1 in 250, tincture of iodine, or pure carbolic acid should be used, that is in cases in which there are lacerations or raw, inflamed surfaces. If such lacerations are covered with a false membrane, generally signifying virulent streptococcic infection, they should be touched with a more caustic solution, such as a solution of chloride of zinc (gr. 300 to the ℥j) after local application of cocaine or under general anesthesia. The site of absorption, as a rule, is the placental site, and a specimen of secretion from the cavity of the uterus for microscopical examination and culture should be obtained. The result is of great importance for prognosis as well as having a bearing upon treatment.

When only moderate pyrexia is present, and the temperature does not exceed 102° F., it may be sufficient in the first instance to wash out the uterus with an antiseptic solution. For the vagina perchloride of mercury may generally be used safely twice a day. The strength may be 1 in 3,000 for two or three days, later 1 in 4,000.

If the bowels have not been thoroughly evacuated when pyrexia first appears, a dose of three or four grains of calomel, followed by sulphate of sodium after a few hours, may be given.

Dr. Galabin is of the opinion that an early exploration of the uterus is indicated in puerperal fever and he does not consider the curette equal to the finger for breaking down and removing adherent placenta.

The writer lays great stress on the importance of maintaining strength in puerperal sepsis, by abundance of liquid nourishment given at short intervals of not more than two hours, except during sleep. Milk is the best food, and a fair amount of alcohol should be taken in the form of brandy or champagne. In some severe cases of septicemia Galabin advises injections into the cellular tissue of sterilized decinormal saline solution, a pint or more at a time.

As to the use of antipyretics in puerperal fever, the writer concludes that quinine in full doses is the most valuable. Perchloride of iron in rather large doses is also a valuable remedy, but other antipyretics are generally to be avoided on account of their depressing effect, although one of the synthetic analgesics may be useful for the relief of pain. Strychnine is valuable when there is a rapid and falling pulse, but opium and morphine are, as a rule, contraindicated. If, however, pain from localized peritonitis prevents sleep, morphine with atropine may be given hypodermically.

Galabin condemns the growing custom in Europe and in America of dealing with puerperal septicemia by operation in the more acute and early stage, and points out that up to the present hysterectomy for sepsis in the puerperium has proved a very dangerous operation. He concludes that hysterectomy has for the present a limited field in the treatment of puerperal fever, and thinks that abdominal section may be undertaken with a much better hope when there is a reason to suspect a pyosalpinx. When diffuse peritonitis has set in, abdominal section can hardly be urged. "The best chance," says Galabin, "in such a condition is to wash out with saline solution, empty the intestines by an incision if they are much distended, and place drains of iodoform gauze or large tubes in the pelvis and lumbar fossæ." When peritonitis is just commencing, the operation recommended by Pryor of evacuating the uterus, opening the pouch of Douglas from the vagina, and packing the uterine cavity and pouch of Douglas with iodoform gauze, is well spoken of by Galabin.

Finally the writer refers to operation in case of thrombotic septicemia. The proposal has been made either to remove the uterus or simply to ligature the uterine and ovarian veins in which the thrombosis exists. Trendelenburg is the only one who has recorded a successful operation of ligature, and Galabin holds that such an operation can only be regarded as affording a slight chance in a case which may otherwise appear hopeless.

The paper by Dr. Galabin, although perhaps, so far as operative procedure in puerperal septicemia is concerned, somewhat more conservative than many American authorities would uphold, is an excellent presentment of the general subject by a justly renowned obstetrician.

COMBATING TUBERCULOSIS IN PRISONS.

PRISONS afford a fruitful soil for the spread of consumption. This is to a great extent, in the nature of things. Confinement, mental depression, and the absence of social life, are apt to lower an individual's vitality and render him prone to tuberculosis. In addition, many prisoners are in themselves insanitary in a high degree, and cell life in the main, is favorable to the dissemination of the germs of tuberculosis.

Dr. J. B. Ransom, physician to Clinton Prison, Dannemora, N. Y., has recently prepared a report for the International Prison Congress of 1905, which has been printed in pamphlet form by order of the Committee on the Judiciary of the National House of Representatives. In order to find out the essential facts relating to pulmonary tuberculosis in prisons, the author formulated a series of questions which were sent to the penal institutions of the

United States, asking for information upon the following propositions: The percentage of tuberculous inmates in the total prison population; what percentage was so on reception; the different manifestations of forms, the mortality, the sanitary conditions of the prisons and workshops, methods of treatment, both preventive and curative, and general suggestions as how best to deal with the situation. There were in all 97 applications for information sent out, and to these 77 answers were returned from prisons in 38 States and 2 Territories. The total population of the 77 prisons reporting was 44,285.

Dr. Ransom, from his own experience, and from suggestions in reports of other institutions, is of the opinion that the means most likely to secure the best results in the direction of prevention and treatment of tuberculosis in prisons may be briefly summarized as follows: (1) Improved construction, housing, and working environment. (2) Larger, better ventilated and lighted prison cells, the abolition of the bucket system, and the substitution of proper toilet facilities. (3) The recognition of the prisoner's receptivity to infection, and the placing of him under the most favorable conditions for resisting the disease. (4) Substitution in so far as possible of other forms of punishment for those of the solitary and dark cell, with starvation diet. (5) Provisions for proper clothing, its cleansing and disinfection, and the administration of spray baths and physical exercise in the open air. (6) The absolute separation from the prison population proper of all tuberculous subjects, together with strict regulation of the spitting habit, the destruction of sputa, the absolute disinfection of beds and bedding after use by one inmate and before transfer to another, the control of dust production in living quarters and workshops. (7) Special wards for the treatment of all active cases. (8) A compulsory law compelling the examination of every person admitted to any penal institution, for the purpose of an early detection of the disease. (9) The construction in every State of a special hospital or sanatorium, favorably located and properly equipped for the treatment of tuberculous subjects, and the transfer of all such to this institution from the jails, penitentiaries, reformatories, and prisons. (10) Provisions for outdoor employment, such as farming, light gardening, etc., for all apparently cured prisoners. (11) The conduct by the Federal Government of an inquiry into the status of tuberculosis in penal institutions of the United States, for the purpose of gaining statistical information of value.

The community at large concerns itself but little with the moral or physical condition of prisoners. So long as the punishment fits the crime, and as the criminal is debarred from exercising his predatory instincts until the expiration of his sentence, the man in the street is indifferent to the treatment meted out to the sinner when under lock and bar. If he were to pause and consider for a short time, however, the fact would dawn on him that both the moral and physical condition of the individual who comes out of prison is a matter of considerable moment to the general public. With the moral phase of the question we have nothing to do here, but it is obvious that if a man or woman be discharged from prison with pulmonary tuberculosis, he or she is a distinct menace and expense to the community. Therefore, from the economic and public health point of view, it would be wise to treat prisoners predisposed to or suffering from consumption, in such a manner that in the first instance the disease may be prevented, and in the second instance the malady may be checked in its progress. Dr. Ransom has indicated the steps to be taken to attain these results, and his report may be studied with advantage by medical men and sanitarians.

THE THERAPEUTIC VALUE OF RELAXING CLIMATES.

A BRACING climate is always the object of laudation, and a relaxing climate is generally regarded as inimical to health. On the whole, however, that is so far as invalids are concerned, it is the dry, stimulating atmosphere which is so injurious to most of the sick, and the humid, equable climate which is beneficial. There are certain maladies which require for successful treatment a stimulating air; but, on the other hand, there are more affections whose cause is favorably influenced by the maligned relaxing climate. Dr. Leonard Williams, in the *Edinburgh Medical Journal* for March, draws attention to this fact, and points out that for a person in robust health a relaxing climate is distasteful, if not absolutely injurious. Metabolism is decreased, appetite impaired, spirits are depressed, and the frame becomes lethargic. Nevertheless, such a climate, despite its disagreeable effects upon the healthy, is possessed of a very much wider therapeutic range than that whose effects are more agreeable.

Putting on one side phthisis, a disease in which the personal equation has always to be considered, and which, according to the condition of the patient, is sometimes benefited by stimulation and sometimes by the reverse treatment, emphysema, on account of the greater uniformity in its prevailing type, is instanced as a disease in which climate has great influence. A bracing climate is contraindicated in the treatment of this disease, because the difficulty of adequately oxygenating the blood causes such patients to suffer acutely from cold and their general condition prevents them from adapting themselves readily to changes of temperature. A relaxing climate, on the contrary, suits those afflicted with this malady, since, in the words of Dr. Williams, "the moisture in the atmosphere acts as a direct sedative on the respiratory passages, while at the same time providing against the frequent and wide variations of temperature which prove so trying."

Chronic nephritis, again, whether of the tubal or interstitial variety, is greatly benefited by a relaxing climate. The excretory power of the kidneys being impaired, more than their fair share of work is thrown on the skin and lungs. A bracing climate, by accelerating and heightening metabolic processes, increases the material of which the excretory organs have to dispose, and consequently further work falls to the lot of the skin and lungs, a result to be avoided. The great essentials in the successful treatment of chronic nephritis are warmth and equability—conditions which are absent in a bracing climate.

In the treatment of chronic diseases of the heart bracing climates are definitely contraindicated. And also in the treatment of degenerative processes affecting the central nervous system, bracing climates

have no place. According to the writer, "Such degenerations, so far as the means now at our disposal are concerned, are incurable; the most that we can do is, while relieving the urgent symptoms, to impede the morbid process, and haply to check it. The vital process must be husbanded, for every exhausted point is immediately occupied by the enemy. Such being the case, the dead level of the relaxing climate is the only safe medium."

Dr. Williams' defence of the relaxing climate for perhaps the majority of those who are sick is able and well timed. It is a question open to argument whether many consumptives are not injured by being sent to bracing climates, and, at any rate, it is quite clear that for many diseases a relaxing climate is indicated.

Prevention of Live Burial.

Although evidence gathered from many sources, especially from the mortuary halls established in many European cities, goes far to show that burial of the living must be a matter of the greatest possible rarity, it cannot be denied that under two conditions, viz., in epidemics attended by great mortality and on the battlefield, this frightful contingency might occur. In a recent brochure,[1] Dr. Icard of Marseilles, cites many cases in point, and describes a method devised by himself for the detection of life if this still persists. Starting with the assumption that some slight degree of circulatory activity, however sluggish, is essential for the continuance of life, the author proposes the injection into the muscles of a solution of fluorescein. In cases of apparent death, after a lapse of a certain length of time, through the diffusion of this very powerful stain the skin will assume a deep yellow color and the eyeballs will be colored intensely green. The test takes but a moment to apply and if positive its results are so striking that no special reexamination is necessary, as in the handling incidental to burial, the discoloration would perforce be noticed. If, then, surgeons or even hospital aids would make an injection of fluorescein into every apparently dead body on the battlefield, the burial corps after the battle would have no difficulty in deciding between apparent and real death, and one horror of war, namely, the danger of premature burial, would be eliminated.

The Carbon Factor in the Genesis of Gout.

That excess of uric acid in the system is the chief if not the only cause of gout is a theory the belief in which is perhaps hardly so strong as formerly. In *The Lancet* of February 11, 1905, is a paper by Dr. Shearer, in which he argues that an excess of carbonic acid is the *fons et origo*, if not the *materies morbi* of gout, by altering the composition of arterial blood deleteriously. Dr. Shearer says that, "Gout, arterial sclerosis, and chronic interstitial nephritis, and in general all so-called uric-acid conditions, are inseperably bound up with antecedent conditions, of which the main factor and the common factor is the excess of carbonic acid in the arterial blood." A part of the argument of Dr. Shearer in support of his theory is that exercise has a beneficial effect upon those subject to gout, because it increases the exhalation of carbonic acid from the blood. Dr. Hare, writing on the matter in *The Lancet* of March 18, points out that the weak feature of this hypothesis lies in the fact that exercise increases not only the exhalation but also the production of carbonic acid in the blood. He believes that a progressive carbonaceous accumulation is a common factor of disease and leads under varying conditions to various paroxysmal affections (amongst them acute articular gout), most of which result in relief from the carbonaceous accumulation. The theory is a quite novel and interesting one, and its further investigation might lead to interesting results.

[1] Le Danger de la Mort Apparente sur Les Champs de Bataille, par le Docteur Icard (de Marseille), Vice-président de la Société de Londres Contre le Danger des Enterrements Prématurés, etc. Paris, A. Maloine. 1905.

A Merited Rebuke to the Street Cleaning Department.

In a recent communication to Commissioner Woodbury the Mayor has called public attention in a striking manner to the wretched state of inefficiency to which the street cleaning department of this city has fallen. Ostensibly the letter was written to urge that the men of the department be relieved from Sunday work, but its only effect has been to excite comment upon the filthy condition of the city's highways, and we suspect that this was the Mayor's motive in sending his communication. "I have long thought of recommending to you," he wrote to Dr. Woodbury, "that you endeavor to so systematize the work of your department as to discontinue the cleaning of the streets on Sunday. . . . The city government should respect the prevailing religious sentiment, which disapproves, except in case of necessity or of mercy, of such work on Sunday, and a just solicitude, for the employees dictates that where possible the day should be free to them for religious observance and for rest." Mr. McClellan may be a sabbatarian by conviction, but he has too much sound common sense not to recognize that the cleaning of the streets is a work of necessity as well as of mercy, and that it cannot be dispensed with on any day of the week without serious injury to the comfort and health of the people. What is needed is not less work, but more, and of more efficient character. If the Commissioner takes this rebuke to heart and puts some life and vim into his work, the Mayor will have rendered a signal service to the citizens of this metropolis as well as to himself. The lazy incompetents who now spread the dust over the streets by worn-out tin scoops should be replaced by men who will sweep it up and away on seven days in the week. At present they are merely digging "a hole for McClellan."

Birth Rate and Postponement of Marriage.

This question, which has become one of such great popular interest, is treated of in the *Popular Science Monthly*, for April, chiefly with reference to the effect produced on the birth rate by postponement of marriage. The late Dr. Engelmann and President Thomas of Bryn Mawr, both have claimed that delaying marriage until a somewhat mature age does not affect the birth rate. Recently, Mr. Coghlan, government statistician of New South Wales, would seem to show by figures collected by him that this theory is untenable. Up to 1880 New South Wales, like most young countries, had a high birth rate. Since that period, however, the birth rate of this colony has fallen to 27.6 per 1,000 and the average number of children in a family to 3.6. Mr. Coghlan attributes this falling off to postponement of marriage. When the average number of children is 3.6, a woman marrying at the age of twenty may expect to have five children; at the age of 28, three children; at the age of 32, two children, and at the age of 37, one child.

News of the Week.

A Politico-Cholera Congress in Russia.—The Congress of Russian medical men summoned to meet in Moscow under the auspices of the Pirogoff Society for the purpose of considering prophylactic measures against the expected invasion of cholera was attended by over 1,000 physicians. As had been foreseen, the sessions resolved themselves into what were practically political meetings of the reactionary order, and the bureaucracy was vigorously attacked. The presidents of the congress, Drs. Chinokayeff and Elpatyevski were recently returned political exiles and it is expected that they will be exiled again. A resolution was passed to the effect that it was impossible for them adequately to practice their profession under the present political conditions. When the doctors ordered goods burned because they were believed to carry cholera infection, the speakers said, the local bureaucrats turned the ignorant anger of the poor upon the doctors and allowed mobs to wreck the houses of the practitioners. The bureaucracy published indiscriminate censure of the doctors for alarming the public by taking preventive measures against the cholera, and also censured them for not taking preventive measures after the cholera had broken out. A resolution was passed that a national assembly, the members elected by universal suffrage, should be convened. The last act of the congress was to despatch a telegram to Maxim Gorky, addressed to him as "a valiant defender of the rights of man." After the adjournment of the congress several of those who had taken a prominent part in its deliberations were arrested.

The Governor of Pennsylvania Vetoes Bill for State Camps for Tuberculosis.—Governor Pennypacker has vetoed a bill passed by the Legislature, appropriating $300,000 for the erection of two State camps for the maintenance, treatment, and cure of cases of incipient tuberculosis. He raises the question whether the resources of the State are sufficient to continue in the enlargement of the scope of the charitable work done by the Commonwealth. He takes the ground that if it is the duty of the State to take care of persons suffering from diseases capable of becoming a source of danger to others, and likely to terminate fatally, it may in time become necessary to care also for those suffering from other infectious diseases, such as smallpox, leprosy, cholera, yellow fever, the bubonic plague, typhoid fever, pneumonia, and others. A further objection to the bill is found in the fact that the benefits of its provision are open to rich and poor alike. The bill provided for the appointment of a commission consisting of two physicians and the Forestry Commissioners for the selection of tracts of land, preparation of plans, and erection of buildings, and finally to act as trustees and managers of the institutions. The Governor thinks the work would require the experience of business men and artisans, the medical superintendency being lodged in the hands of physicians. He points out further that if the forestry lands are to be laid bare for the purpose of erecting buildings in one worthy cause, they may in time come to be utilized for many other such purposes. Finally, he believes that the objects of the bill will be better fulfilled by the proposed act for the creation of a State Department of Health with ample powers to carry out plans for the treatment of tuberculosis and the protection of the community from the evils that ensue from the prevalence of this disease.

Tuberculosis in the Joliet Penitentiary.—Investigation of the condition of the prisoners in the Joliet, Ill., Penitentiary, especially as to the spread of tuberculosis, began recently. The close confinement in the small cells, in connection with the idleness that many of the prisoners have been forced to undergo in the last nine months, has resulted in an increase in tuberculous cases of fully forty per cent., according to the statements of the prison officials. The present cell houses are old and small, and are regarded as unsanitary largely because of their narrow limits and close proximity to each other. Plenty of fresh air and exercise, as well as a new cell house, are needed, in the opinion of experts who made the examination. Dr. George W. Webster, President of the State Board of Health, Dr. J. A. Egan, Dr. Palmer, and Professor J. H. Long, of Northwestern University, have started an exhaustive examination.

City's Consumption Clinic.—The clinic for the treatment of pulmonary tuberculosis established a year ago by the Health Department at 967 Sixth avenue, adjoining the department headquarters, has been so successful that it has been decided to open a similar dispensary in Brooklyn about May 1, for which a building at 76 Henry street has already been leased. During the twelve months of the clinic's existence 3,100 patients applied for treatment, making 13,740 visits, a daily average of forty-four patients. Of this number 327 were placed in hospitals and sanatoria, and 610 patients are now under treatment at the clinic. The objects sought for by the establishment of these clinics are the extension of the sanitary control of consumption among the poor by the Department of Health through education regarding the measures necessary to prevent the spread of infection, providing proper food to indigent cases, supervision of the patients at their homes by visiting nurses, etc.

A Quarantine Against Cuba.—The health boards of the Gulf States have issued a quarantine order to the effect that passengers from localities in Cuba other than Havana, must present certificates from representatives of the United States Public Health and Marine-Hospital Service stationed in Havana showing that sufficient time has elapsed from the original point of departure to prevent such passengers reaching any Gulf port in less than five full days from said point of departure. As soon as this action became public the Cuban National Board of Health sent the following cable to Dr. Souchon of the Louisiana State Board of Health: "The Superior Board of Health protests against your action discriminating against territory of the republic outside of Havana. We are in constant touch with all districts, and we know that they are just as free from quarantinable diseases as is Havana. We had taken for granted that this was well known to all sanitary authorities. We trust, therefore, that you will reconsider your action." Dr. Finlay, Chief Sanitary Officer of Cuba, says that there is no justification for this discrimination against the island outside of Havana, for the entire country is under constant effective sanitary control. When a case or suspect of a quarantinable disease occurs anywhere in Cuba, the local officer is compelled to telegraph the fact at once to the chief sanitary officer in Havana. The latter then orders the provincial inspector for the corresponding province to investigate the case. This inspector telegraphs the result of his investigations and sends by mail all the data about the case, and these are submitted to the board of experts in Havana. If the diagnosis is confirmed, or the suspicions are maintained, one or more of the experts are sent to the spot, and every measure is taken to prevent the spread of the disease.

Osteopaths not Physicians but Liable for Malpractice.—The Supreme Court of Missouri has decided that osteopaths are not physicians and surgeons under the laws of the State, but if they pretend to treat diseases they must be held responsible for their acts. The case came to the supreme court from a lower court, where a young girl, through her guardian, brought suit against one of the leaders of the School of Osteopathy for $10,000 damages for malpractice. She had been treated by him for hip disease, and alleged that he had done her great harm. The lower court sustained a demurrer to the evidence and rendered judgment for the defendant. The supreme court reversed that judgment, and held that the plaintiff was entitled to damages.

A Tapeworm Cure for Tuberculosis.—A recent consular report announces the discovery in Buenos Ayres that the tapeworm is inimical to the tubercle bacillus. A person suffering from consumption is reported to have been restored to perfect health after getting a tapeworm, and the injection of tapeworm juice arrested the progress of the disease in the most advanced cases. There are great possibilities in the exploitation of this theory.

A Blue Germ.—A special to *The New York Times* of April 10, announces that the spotted fever germ has at last been run to cover. To Pittsburg belongs the honor of capturing the bacterium, but with rare magnaminity and moved by an exquisitely developed ethical sense, the bacteriologist who did the feat is willing that this city should share in the glory; he has declared that "He would consult with the New York authorities concerning it, as the victim from whom the germ was taken came from New York a week ago, suffering from the disease." The discovery was not the result of accident but was the reward of reasoning based upon a well-founded suspicion that the spine was affected. When the bacteriologist "saw that the boy could not live he sank a hypodermic syringe into the spinal column of the boy and extracted some fluid, which was examined and the germ was located. It was blue and shaped something like a coffee bean." It must also have been of considerable size, if it was necessary to plunge the whole of a hypodermic syringe into the spinal cord in order to extract it.

The Germs of Smallpox and of Syphilis.—An extraordinary session of the National Board of Health was recently held in Berlin in order to give a hearing to Dr. Johann Siegel who claimed to have discovered the microorganisms both of smallpox and of syphilis and desired to submit his proofs to official scrutiny.

The American Gastroenterological Association will hold its eighth annual meeting at the Academy of Medicine in this city on April 24 and 25, 1905, under the presidency of Dr. S. J. Meltzer. A very interesting program is announced. The annual dinner will take place at Delmonico's on the evening of April 24. The secretary of the association is Dr. Charles D. Aaron of Detroit.

A Specialists' Course on Otology.—Dr. W. S. Bryant has instituted at the Post-Graduate School a course of practical instruction in diseases of the ear. Each course will last for six months.

The Membership of the New York Academy of Medicine has reached the limit of one thousand, and now, for the first time in the history of the society, there is a waiting list.

The British Opticians, following the example of their brethren in New York State, are getting busy and are preparing to introduce a bill in Parliament for the registration of persons who profess to test the eyesight.

Otero County Medical Society.—The physicians of Otero Co., N. Mex., have organized a county society with the following officers: *President,* C. H. Waldschmidt; *Vice-President,* O. W. Miller; *Secretary,* E. B. Van Arsdel; *Treasurer,* G. C. Bryan. Dr. J. R. Gilbert was chosen as a delegate to the Territorial Medical Association, which holds a meeting in Santa Fé in May.

The Eighth International Congress of Veterinary Medicine will be held in Budapest the coming summer. A full program is expected, twenty-two papers being already in hand, and adhesions to the congress are coming in rapidly. The secretary-general is Dr. Etienne de Ratz of Budapest. Dr. Salmon, Director of the Bureau of Animal Industry at Washington, is the American representative.

Railway Casualties.—A report of the railroad accidents in the United States during the months of October to December, 1904, has been compiled by the Inter-State Commerce Commission. It shows that, in that quarter, 53 passengers and 189 employees were killed, and 1,430 passengers and 1,868 employees were injured; a total of 242 persons killed and 3,298 injured in train accidents. Other accidents to passengers and employees, not the result of collisions or derailments, bring the total number of casualties up to 14,978—95 killed and 14,027 injured. The report indicates a decrease of 175 killed and 624 injured, as compared with the preceding three months.

Inspection of Milk Stations.—The Health Commissioner of this city has recently made an inspection of the milk stations along the line of the Delaware, Lackawanna and Western Railroad, at the request of the president of the company, and will make certain recommendations which the company's officials will carry out to the best of their ability. The railroad does not own the milk stations, but by refusing to carry milk from producers who do not observe sanitary rules can compel better conditions.

The Garcia Memorial Fund.—The total amount collected for the Garcia fund is announced to be nearly £800 ($4,000).

Ashland County, O., Medical Society Reorganized.—For the purpose of coming into closer contact with the State and national associations, this society has been reorganized with the following officers: *President,* Dr. D. S. Sampsell, Ashland; *Vice-President,* Dr. J. J. Fridline, Ashland; *Secretary,* Dr. R. C. Kinneman, Ashland; *Treasurer,* Dr. W. H. Wirt, Loudonville; *Board of Censors*: For three years, Dr. D. E. Pocock, Jeromeville; for two years, Dr. Budd, of Perrysville, and for one year, Dr. A. L. Sherick, Ashland. *Delegate* to the Ohio State Medical Association, Dr. F. V. Dotterweich, Ashland. *Alternate,* Dr. C. B. Scott, of Loudonville.

The Cerebrospinal Meningitis Epidemic has apparently passed its acme in this city, and a decrease in reported cases and deaths for last week is announced.

Louisville, Ky., Medical and Surgical Society.—At the annual meeting of this society on March 20, the following officers were elected: *President,* Dr. W. H. Coleman; *Vice-President,* C. W. Hibbitt; *Secretary,* Dr. John K. Morris; *Treasurer,* Dr. Dunning Wilson.

College of Physicians of Philadelphia.—At a stated meeting held April 5, a symposium was held on "Medical Reminiscences of the Civil War," and it was participated in by Drs. S. Weir Mitchell, W. W. Keen, and John S. Billings.

The St. Lawrence County, N. Y., Medical Society will hold its annual meeting at the Arlington House, Potsdam, N. Y., April 18, 1905, under the presidency of Dr. E. M. Somers.

The Texas State Board of Medical Examiners will hold its next meeting in Austin, Texas, May 2, 3, 4, and 5, 1905, for the examination of applicants and transaction of other business. Further information may be obtained by addressing the secretary, Dr. M. M. Smith, Austin, Texas.

Council of Medical Education.—April 20 there will be a meeting of the Council on Medical Education of the American Medical Association, in Chicago, to which representatives of licensing and examining boards of the various States and Territories, as well as representatives of college associations, have been invited. The present status of the laws of the various States and Territories, with reference to licensure, will be presented by Dr. A. D. Bevan; while Drs. J. A. Witherspoon of Nashville, Tenn., and Victor C. Vaughan, of Ann Arbor, Mich., will discuss the subject of preliminary education. Drs. Chas. H. Frazer and Wm. T. Councilman will present reports on the curricula of medical colleges.

Cincinnati Academy of Medicine.—At a regular meeting on April 3, papers were read on "History of Medical Libraries in Cincinnati," by Dr. H. W. Bettman; "Their Value," Dr. D. I. Wolfstein; "Their Future," Dr. C. R. Holmes. A committee was appointed to represent the Academy, Drs. John A. Thompson, H. J. Whitacre, and A. B. Thrasher, to confer with the committees of the Cincinnati Hospital staff and of the Medical Library Association, as to the best means of getting the various libraries into one central collection.

Dr. David Linn Edsall has been elected assistant professor of medicine in the University of Pennsylvania.

The West Virginia State Medical Association will hold its thirty-eighth annual meeting at Wheeling on May 24-26, 1905. Those who intend to present communications are requested to send the titles of the same to the secretary, Dr. William W. Golden, Elkins, W. Va., not later than May 3.

Obituary Notes.—Dr. William Henry Doughty of Augusta, Ga., died on March 27, at his home in that city. He was born in Augusta, February 5, 1836. He began the study of medicine in the fall of 1852, in Augusta, attending two courses of medicine at the Medical College of Georgia, now the medical department of the University of Georgia, and was graduated from this institution in March, 1855. He served throughout the Civil War in the medical corps of the Confederate Army. From 1868 to 1875 he was professor of materia medica and therapeutics in the medical faculty of the University of Georgia. He was a member of the Georgia Medical Society, of the American Medical Association, of the American Public Health Association, and of the Tri-State Medical Society of Alabama, Georgia, and Tennessee.

Dr. Theodore Sittel, formerly of Cincinnati, died on March 25 at his home in South Norwood at the age of seventy-six years. He was born in Germany where he received his medical degree in 1854, settling in Cincinnati the following year. He was one of the founders of St. Mary's Hospital.

Dr. Fabius Fox of East Baltimore, Md., died suddenly on March 29, at the age of forty-two years. He was born in Russia, and was graduated from the Baltimore University School of Medicine in 1898.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ANTHRAX—RHEUMATIC DISEASES—STARVING SCHOOL CHILDREN—GARCIA—HOSPITALS—IRISH GRADUATES—JUBILEE OF DR. A. H. T. WATERS.

London, March 24, 1905.

The Milroy lectures at the College of Physicians have been given this year by Dr. T. M. Legge, who has devoted them to an elaborate account of industrial anthrax. As a medical inspector of factories, Dr. Legge had full opportunities of studying the subject, and of these he availed himself to the full. He gave the result of his studies in the three lectures, in which he discussed the disease in all its bearings. I shall only touch here the serum treatment, which is the one of greatest moment to practitioners, and which seems to afford good hope in this formidable disease. Dr. Legge was not content to study it here, where only twelve cases have been reported, and in only four of these was it solely employed. But he went to Italy, and Professor Sclavo placed every information at his disposal and let him see all the stages in the preparation of his serum in the Pathological Institute of the University of Siena. He went to Milan and examined Rachetti's great horsehair factory, where 700 workers are employed. There a physician attends every morning, and a bacteriological laboratory is fitted for his use, and a supply of serum kept, so that cases are caught and treated in the earliest stages. The head of the firm said he had now no fear of anthrax among his workpeople as he has seen so many successes. The claims of the serum treatment Dr. Legge summarized thus: (1) In large doses it is innocuous; (2) it can be borne injected into the veins; (3) taken in early stage no case is fatal; (4) some are saved when the state is critical and the prognosis almost hopeless; (5) injected into the veins the serum arrests the edema and reduces danger of suffocation when the pustule is on the neck or face; (6) used early it reduces to a minimum destruction of tissue; (7) in some situations of the pustule, as the eyelid, serum is to be preferred to any other treatment; (8) patients treated with serum become convalescent in a few hours; (9) in internal anthrax the only hope is the serum injected into the veins The serum is usually followed by a rise in temperature, often to 105° F. or over, but with this the patient's condition is improved, and Dr. Sclavo considers it as a favorable prognostic indication.

Prof. Sheridan Delépine, lecturing to medical officers of health on the increase of anthrax, attributed the cause to concealment on the one hand, and overlooking cases on the other. From his experience in the Manchester University Laboratories he urged a more complete system of notification and greater coordination of the work of sanitary authorities, the veterinary and factory departments, market committees, and police. He suggested paying a small fee to farmers and veterinary surgeons for early notification, and penalties for wilful concealment of cases. If the disease were allowed to spread on our farms we must expect cases of human anthrax to become more frequent.

Rheumatic maladies, under various names, are always with us, and discussions are continually arising as to the exact position of this or that affection in the so-called rheumatic catalogue. Dr. Hale White has detailed to the Clinical Society a case which he calls "acute rheumatoid arthritis," and at the same meeting Dr. Bertram Abrahams read a paper on "Arthritis Deformans and Its Allies." With regard to his acute case, Dr. White said such an illness should be sharply separated as a distinct disease from chronic rheumatoid arthritis, osteoarthritis, arthritis deformans, and chronic articular rheumatism. The disease he described is most prominent in the proximal phalangeal joints and wrists, symmetrical with much swelling beyond the joints, fusiform, sometimes creaking due to thickening of the synovial membrane, leading to immobility and muscular atrophy, but no lipping or bony outgrowths. In a few weeks most of the joints become affected, and the woman (generally the patients are young women) bedridden. Temperature rises in the evenings to 100° or 102° F. In contrast with rheumatic fever, the swelling remains after the acute stage, and fresh attacks occur, each increasing immobility, and making the patient a chronic invalid. These attacks may diminish in severity, and ultimately the patient only suffer from the deformities left. Dr. White considers the disease originates in the synovial membranes and tissues round the joints, the cartilages being unaffected; the bones are unusually transparent to the *x*-rays.

Turning to Dr. Abrahams' paper, he selected the term "arthritis deformans" as the least unscientific and as the one most in use in America and on the continent. He grouped four maladies under it: that described by Still in children, associated with enlarged spleen and lymphatic

glands; senile osteoarthritis, a degenerative process which might come on in normal joints or follow in those crippled by other forms of rheumatism. The two remaining groups —acute and chronic arthritis deformans—were probably different forms of the same, and infective or toxemic in nature, the poison in acute cases flooding the joints, but in chronic less in amount though more prolonged, the changes then being more degenerative than inflammatory. The acute and chronic merge, and there are numerous intermediate forms. The brunt of the disease falls on the nervous system. Dr. Abrahams showed skiagraphs and photographs of acute and chronic cases, and of Charcot's and Still's diseases.

Dr. Toogood said the cases described by Dr. White were as common in men as in women, and not easy to distinguish from gout. Drugs he found useless, and advised generous diet, meat and tonics. He found some signs of rheumatoid arthritis at every post-mortem on a person over 65.

Dr. A. E. Garrod said Still's disease was very fatal. Not so adult cases. Excluding senile arthritis, we have in adults two distinct diseases, acute cases such as that of Dr. White, which might sometimes smoulder on for years. Distinct from this was multiple osteoarthritis, affecting joints of thumb and metacarpus, and causing less damage. He suspected a third form, far less common, with deformity as its chief feature, and not much enlargement of the joints. Other cases were due to infections, many of them puerperal.

Dr. Luff thought rheumatoid arthritis due to infection from the intestinal tract, and carbonate of guaiacol the best drug, as the guaiacol was set free in the intestines. The two hands were symmetrically attacked, and there was sweating of palms and soles, two conditions absent in gout, which latter did not spread to the vertebræ or temperomaxillary joints.

Dr. Preston King considered rheumatoid arthritis a bastard form of rheumatism, due to the action of the poison on the nervous system.

Dr. Blanc of Aix-les-Baines had found the serum injected for diphtheria in patients who were also subjects or rheumatoid arthritis had seemed to benefit this as well as the diphtheria. He then tried the serum on ten cases of rheumatoid arthritis, and all improved, two getting well. The arthritis of tuberculous patients he found aggravated by baths.

Dr. Ewart attributed various forms of the disease to toxemia, the poisons being either microbes or autotoxins.

Dr. Ll. Jones of Bath had known six cases to follow gastric ulcer.

Dr. White, in his reply, said the spindle-shaped joints and thinning of the ends of the bones were always present in the cases to which he had drawn attention. The primary lesion was in the synovial membranes and the soft tissues around the joints. He doubted the power of any drug to disinfect the intestinal tract.

Dr. Bertram Abrahams also replied. He found guaiacol useful. He saw Ringer treat some cases years ago with diphtheria antitoxin, and one of them seemed decidedly benefited.

The sentimental public has been holding high revel over the alleged hunger of starving school children, and the sensational papers have been duly gushing over a revelation which turns out to be a mare's nest. Sir John Gorst, who has been actively advocating the duty of the State to feed as well as educate the scholars, in company with the Countess of Warwick and Mr. Macnamara, M.P., paid a surprise visit to a board school in Lambeth, satisfied themselves that a large number of the scholars were in a state of semi-starvation, and communicated their discovery to the guardians, and then to the press. The public was duly shocked, and like these amateur inspectors did not pause for a reply. But the guardians at once investigated the matter, and the result is that the inexperienced, self-appointed investigators were duped. They asked the children who had come to school without breakfast to hold up their hands, and many did—no doubt expecting the visitors were going to give them an extra treat. They then called upon guardians to give immediate relief to the parents. But the guardians sent their officer to visit the homes of the children. In some cases his visit was resented, in others the parents were at work, in one or two they were previously receiving relief, in some the boys said they got up late and left breakfast to be in time for school. Lastly, some parents said they sent them without breakfast, as they knew if they did it would be given them, as other people's children were given things, and why should not theirs? which is a good instance of the independence of a certain class as disitnguished from the respectable workman. The earnings of these families varied from 20 shillings to 73 shillings per week, and so the gush of the aristocratic socialists has been shown to be absurd.

Let me add a word or two to my last week's report of the Garcia commemoration. In the morning the hale octotenarian was received by the King at Buckingham Palace and invested with the Victorian Order. In the afternoon he took the chair with remarkable vigor for a man of his years, and in the evening he responded to the toast of his health in an equally surprising manner. It is a pleasure to think he sustained the excitements of the day without undue fatigue. The menu of the dinner was adorned with two striking portraits—one taken about the time of the invention of the laryngoscope, the other taken for the occasion.

The Duchess of Albany attended the annual meeting of the National Hospital for the Paralyzed and Epileptic on Tuesday. The institution is in great need of funds—another £5,000 a year. The chairman, Mr. Power, said that a committee of ladies had brought about a saving of £2,000 a year in housekeeping and domestic expenses. The Duchess responding to a vote of gratitude for the interest she takes in the hospital, thanked the chairman for all he had done for it, and while regretting his vacating the post, wished him every success in his new office—the secretaryship of King Edward's Hospital fund.

The Earl of Derby is president of the Royal Sea-Bathing Hospital, and took the chair at the annual meeting on Wednesday. The income had fallen short of the expenditure by about £1,300, and if patients had been admitted free the deficiency would have been £4,700. His Lordship thought the time was coming when only curable cases should be admitted, and perhaps in years to come an institution might be attached to it where the incurable cases could spend their last days with all the amelioration possible. Sir H. Lennard, chairman of the hospital, announced that the Earl had handed him a cheque for £1,000.

The Mount Vernon Hospital for Consumption appeals for £100,000. At its two houses it provides 250 beds, but 110 are empty for want of funds. There is no reserve fund. Too much building seems to have been undertaken.

There was a large attendance at the dinner of the Irish Graduates' Association, when Sir W. Whilla presided, and was supported by the presidents of the Irish and English Colleges of Surgeons, the director-general, A.M.D., various officers, and others. Mr. Chance, P.R.C.S.I., complained of the restrictions of the London hospitals, and urged that surgery could not be limited by geographical bounds.

The Liverpool Medical Institution made its meeting on the 16th inst. one of congratulation to Dr. A. T. H. Waters, on his attaining his jubilee of membership of the institution of which he is a past-president. Dr. Waters gave an address on his reminiscences in the profession, which he entered nearly sixty years ago, and during many of which he held a leading position in the Liverpool school.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

PRACTICAL NOTES ON APPENDICITIS PNEUMONIA IN THE TROPICS—DISEASES IN THE HIGHLANDS OF BENGUET—SMALLPOX AT SHANGHAI—VACCINATION OF THE MOROS.

MANILA, P. I., February 16, 1905.

At the February meeting of the Manila Medical Society a paper was read by Major J. M. Bannister, U. S. Army, entitled "Practical Notes on Appendicitis and Its Treatment." The subject was treated in an exhaustive manner. The etiology, the symptomatology, and the many complications were discussed at length. Under the head of treatment the author stated that all cases seen within forty-eight hours of the beginning of the disease should be operated upon immediately. He stated, as evidence that he practised what he preached, that he had carried out this course in a case of appendicitis occurring in his own family. He preferred the McBurney incision because of the lessened danger of postoperative hernia. The simplest plan for the removal of the appendix itself was by ligation, excision, and cauterization of the stump with carbolic acid. Judging from the seventy odd cases that had come under his observation since he has been in the Islands he was led to believe that appendicitis ran the same course as in the United States, and that the operative results were equally good. In the discussion which followed, Professor Watson, of the Adelaide, Australia, Medical School, who was a guest of the Society, stated that he fully concurred in all that had been stated by the author, and that the subject had been so fully covered that there remained very little to add. Dr. McDill stated that after reading the papers and the discussions which took place at the last meeting of the American Medical Association, and after listening closely to the author's paper, he had failed to observe that any of the writers had mentioned the desirability of seeking for a fecal concretion in perforative cases of appendicitis. He cited a number of instances in which such concretions had been found to be the cause of subsequent fecal fistulas.

Dr. Moulden, the medical officer of Bilibid prison, showed a large number of charts and histories and specimens from

cases of lobar pneumonia, and stated that at future meeting of the Society he hoped to be able to show in a paper that lobar pneumonia in the tropics differed from that in temperate climates.

A paper entitled "Notes on the Diseases Encountered in Baguio and the Neighboring Highlands of Benguet During the Year 1903-4," was read by the secretary, Dr. J. B. Thomas being the author. He stated that Baguio was a small village situated in the province of Benguet at an altitude of about 5,000 feet above sea level. It is at this place that the Civil Government proposes to establish its summer capital. The temperature ranges from 40° to 70° F. With the exception of a few weeks this represents the daily difference between the night and day temperature. The severe rainy season lasts about three months in the year. Pine trees are abundant and the vegetables which ordinarily grow in temperate climates may be successfully raised. He had seen some cases of beriberi, but they had been contracted in the lowlands, and in his experience he had never seen a case of beriberi at an altitude above 3,000 feet. He also did not believe that a non-nitrogenous diet was a cause of the disease. He could not trace any cases of dysentery as having originated in Baguio. The various forms of intestinal worms were found in the same proportion as elsewhere. Catarrhal inflammations of the nose, throat, and upper air passages were rather common. He thought the climate suitable during nine months of the year for such cases of pulmonary tuberculosis as it was not practicable to send to the United States on account of extreme feebleness or other equally important reason. Yaws was a very common affliction. In the discussion, Major Carter, of the Board of Health, mentioned that a number of cases of beriberi had occurred several years ago among the inmates of the Alabama Insane Asylum who were being subsisted upon a rich nitrogenous diet, and who, so far as known, had not come in contact with any cases of beriberi. The neighborhood was reported to be entirely free of the disease.

The smallpox outbreak in Shanghai is one of the worst that has occurred in the Orient in recent times. According to the reports there were some weeks during December and January in which 200 cases were reported. Estimates made by conservative medical men resident of Shanghai are to the effect that one additional case occurred for each one given by the official statistics. Eight vessels are known to have had smallpox break out after leaving Shanghai. Among these were the German mail steamer, and the French mail steamer *Australien,* upon which General Stoessel, of Port Arthur fame, was a passenger. One vessel arrived in Manila from Shanghai which had a case of smallpox on board which developed fourteen days after leaving Shanghai. The great danger of shipping conveying the infection to all parts of the world will be readily appreciated. The Hongkong quarantine authorities, who ordinarily are slow to require quarantine inspection of incoming vessels, now board all ships arriving from Shanghai before permitting them to discharge passengers. The United States quarantine authorities require that the crews and steerage passengers bound for Philippine ports be vaccinated before leaving Shanghai.

Upon further investigation the Insular health authorities found that the reports of the smallpox occurring on the island of Marinduque were very much exaggerated. In Manila there were a few cases during January; they practically all occurred among transients. General Wood recently requested that he be furnished with a corps of vaccinators in order that he might commence the vaccination of the Moros. This experiment is being watched with much interest because the Moros are among the wildest tribes in the Philippines and in many respects resemble the American Indian.

TREATMENT OF CEREBROSPINAL MENINGITIS.

To the Editor of the Medical Record:

Sir: In the following epitome, it is the intention of the writer to sift the chaff from the wheat, and give an outline of the treatment of this disease.

Ice bags are uncalled for; they are harmful, and at best I consider them of the purgatorial placebo order.

Occipital vesication, effected by the use of Spanish fly blister, 3½ by 7 inches, should be resorted to at once, without delay, removing what hair is necessary. Do not remove the blister too soon. Keep a running sore for a week or two by poulticing, etc. This all-important matter should not be neglected; herein lies success.

Unload the primæ viæ with 15 to 20 grains of calomel (adult dose), followed in three hours by a large dose of magnesium sulphate. This is obligatory.

To jugulate the disease in conjunction with the blister the following formula has its merits:

℞	Potassii bromidi	ʒi
	Chloral. hydrat	ʒii
	Ant. et pot. tart	gr i
	Tr. aconiti	ʒi
	Aq. cin	ʒii
	Aq. font., q. s. ad	ʒvi

M. Shake well and give a teaspoonful or two in a little water every two to four hours, day and night, and oftener if necessary. Also acetanilid 5 grains in capsule or solution every four to eight hours; this is an acknowledged cerebrospinal sedative. Chloroform inhalation is frequently called for; its proper use is a Godsend. Hypodermicsc should be avoided if possible.

An easily assimilated and nutritious diet should be strictly enforced.

The advocacy of this line of treatment is based on over forty years' experience. A few years ago my daughter (adult) was stricken down with this terrible disease in its severe form. Suffice it to write, she made a handsome recovery.

John T. DeMund, M.D.
Ridgewood, N. J.

CALCIUM SULPHIDE IN DIABETES AND GINGIVITIS.

To the Editor of the Medical Record:

Sir: Referring to my article on diabetes in the Medical Record of June 11, 1904, I beg to make the following addition: Having had excellent results in the use of calcium sulphide in carbuncles and furuncles, the frequent symptoms of diabetes, it occurred to me that this drug might also be used successfully for gingivitis, another symptom of diabetes, and for diabetes itself. From my experience with the drug I now strongly believe that it is really good in these diseases. I used it to great advantage in six cases, and Dr. Charles Vetter, lecturer on materia medica in the New York College of Dentistry, to whom I suggested its employment, in two more cases of gingivitis; his two cases and two of my cases were purulent, while the rest showed induration. The eight cases were the only ones treated by us.

There is hardly ever any local treatment of gingivitis followed by a good result, and this is quite natural, since gingivitis is not only a local disease, but usually the manifestation of abnormality of the entire system, which requires a general treatment. Calcium sulphide seems to answer this purpose better than any other drug. But one must be careful in the selection of this drug, and if it comes in hard tablets or pills, directly before using it, it should be broken into a few pieces. Of course, the paucity of the mentioned trials is not quite a sufficient proof, but it invites to some more.

Louis Barkan, M.D.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 6, 1905.

Surgical Treatment of Nephritis; a Résumé.—Paul Thorndike reviews the statistics of the surgical treatment of nephritis, describes the technical features of the operation and analyzes results. He finds four clinical conditions given as indications for the operation: (1) Albumin and casts associated with movable kidney; (2) cases of true nephritis with the same association; (3) Chronic interstitial nephritis, and (4) Diffuse nephritis. Doubtless in many of the cases so far collected the albumin and casts were manifestations of a temporary condition brought about by tension of the renal pedicle, torsion or kink in the ureter, or some similar mechanical condition resulting from the renal mobility. In these cases the operation has removed the cause and its manifestations have disappeared. Doubtless, also, some of these cases may have been reported as cases of true nephritis, although the conditions involved have not existed long enough or continuously enough to have brought about permanent degenerative changes in the renal tissues. In others a true nephritis doubtless exists associated with the renal mobility. Both these classes of cases are fit subjects for operation, but whether the individual patient under consideration demands a fixation as well as decapsulation must always be a matter, and often a difficult matter, for the judgment of the surgeon to decide at the moment. He believes that evidence gathered at post mortem in persons who have been operated on but have died at different intervals from causes entirely apart from the kidneys, proves that a new capsule forms within a few weeks of the operation, but finds no positive evidence of the establishment of a collateral circulation sufficient in degree to materially affect the renal.

Diet in Nephritis.—H. Jackson gives the following dietary for patients with renal disease. Breakfast: Cereal with cream, egg, bread and butter. Very weak coffee with

much cream, fruit, glass of milk. Dinner (preferably in midday): One ladleful soup, little fish, one slice meat, one vegetable. Dessert: Essentially fruits; "simple" children's puddings may be taken as desired. Supper: Cold meat, broiled fish, bread and butter, milk. In cases in which the condition is not good milk in the forenoon and at bedtime is indicated. Koumyss in my hands has rendered very material service. It is the author's experience that in cases of this class the exhibition of a considerable quantity of water, especially alkaline waters, is of value. Since the publication of Van Noorden's work on the subject he has made trial of reducing the fluids, and his results have not been favorable. In general terms it may be said that in acute nephritis the diet must be cut down to the smallest amount compatible until the maintenance of a fair degree of bodily strength; the patient must be fed as one would feed in an acute febrile disease. In chronic cases, the diet must be so limited as to maintain a proper equilibrium. As much cream and fresh butter should be taken as can be digested. In those cases of the pure interstitial type with the excretion of a large amount of water and the presence of an occasional type the diet should be simple and nourishing. No stimulating food, wines or liquors should be allowed.

New York Medical Journal, April 8, 1905.

Spondylose Rhizomyélique; a Study of the Relative Frequency of Spinal Involvement in Rheumatoid Arthritis, with Autopsy Findings.—Fourteen cases are reported by D. J. McCarthy, who makes a brief mention of the cases of rigidity of the spine reported since von Bechterew's revival of the subject in 1893. His own paper discusses spinal rigidity (1) As a separate and distinct clinical and pathological entity and (2) as a local manifestation of rheumatoid arthritis. His personal conclusions are as follows: (1) That ankylosis and rigidity of the spinal column is a frequent manifestation of advanced rheumatoid arthritis; (2) That it may develop early in the course of the disease and be associated with irritative root symptoms; (3) That if the disease described by von Bechterew is to be considered as a distinct clinical entity separate from rheumatoid arthritis, it should only be diagnosticated as such after the disease has progressed over a considerable period of time without involving joints other than those of the spinal column; (4) That we are not able at present to differentiate from rheumatoid arthritis that large group of cases, reported by Marie and others, where the rigidity of the spine is associated with changes in the hip and other joints.

Asepsis and Antisepsis in Obstetrics; also "Sterile Gauze" and "Sterile Water."—J. Milton Mabbott reiterates his plea for immediate repair of perineal lacerations and his belief that the best results cannot be obtained without the systematic use of antiseptics. A soap and water solution is but weakly efficient in this direction but does not meet all requirements. He says there is no question whatever of the danger of sepsis being greater in an infected closed wound than in an infected open wound. And since we believe that microorganisms in the contiguous skin or air are occasionally responsible for infection, we too should have some hesitation in sewing up the perineum without disinfection even in a cleanly conducted case. But why should we not cleanse the wound with an antiseptic solution and seal it from later infection? So far from being a cause of sepsis perineorrhaphy thus becomes a valuable means of prevention. While there is one practitioner openly advocating the open treatment of the perineum, the subject is worthy of our attention lest others be misled. The expression "sterile" gauze is a misnomer. It cannot remain sterile after the unavoidable exposure incident to its removal from the sealed container and introduction into a wound or cavity. "Sterile" water exposed to the air is sterile only while it is too hot for use in midwifery. By the time it has cooled sufficiently for use, many germs will have fallen into it from the air and will remain undestroyed at the lower temperature. The paper closes with a description of the obstetric technique followed by the author.

Medical News, April 8, 1905.

The Function of the Parathyroid Glands.—W. G. Maccallum and C. F. Davidson recount the results of numerous experiments on dogs. They find that when the parathyroids more rapidly to death and with less tendency to the development of emaciation and cachexia than in cases in which the thyroid is removed at the same time. Nevertheless, a considerable proportion of those cases do develop violent tetany—tetany which quickly leads to the death of the animal—and in practically all the cases the symptoms began quite as soon as in the other cases. In a series of six experiments no effect on the tetany was produced like thyrodectomy, the parathyroids having been previously removed. In one the tetany was slight before the removal of the thyroid, and disappeared entirely after it. In one the tetany, also slight, continued, but became progressively milder until it disappeared just before death, which occurred four days later. The authors, therefore, regard the tetany not as the result of a disturbance of the thyroid from the loss of the influence of the parathyroids, but as the direct result of the loss of parathyroid function, especially since it may be directly cured by injection of parathyroid emulsion in the absence of the thyroid.

American Medicine, April 8, 1905.

The Optic and Ocular Factors in the Etiology of the Scoliosis of School Children.—George M. Gould says that 27 per cent. of all European schoolchildren, probably of American also, have lateral spinal curvature, and the fact constitutes a source of disease, suffering, and death greater than many others about which the profession and the public are infinitely more concerned. But the cause of lateral curvature remains a most perplexing mystery. In some way or other orthopedists and hygienists usually charge it to school life, posture in study, and, more closely, to the writing posture. The slanted style of handwriting is by many believed to be the source of the mischief. Dr. Gould sets forth the reasons why it is the consequence of visual function—a certain proportion being due to a peculiar axis of astigmatism, compelling a lifelong canting the head to one or the other side in order to see plainly. But a larger number of cases arise in the habitual bending of the head and body to the left in writing. This necessity of bending the head to the left is caused by the impossibility of seeing "the writing-field," or what is being written when the paper is placed, the pen held, and the body postured as commanded by all teachers and writing masters of the past. This is illustrated by photographs, and can be demonstrated by observation of others or by one's self in writing. The right eye (one is right-eyed, as he is right-handed) must see the writing-field. The habitual cervical curve, it is suggested, with convexity to the right, neglected by orthopedists, by compensation creates the secondary spinal curves lower down. The prophylaxis and cure consists in placing the paper opposite the right shoulder, 14 inches from the eyes, and upon a desk leaf slanted at least at 30°, whereby the body may be kept erect, hygienically posed, and the writing plainly seen. If this is impossible because of old school desks, a peculiar angled penholder devised by Dr. Gould may be used. The Oriental style of grasping the holder may be used, or, as somewhat common, held between the first and second fingers. If this theory is true, the Oriental schoolchildren should be relatively free from spinal curvature.

Tendon Transplantation.—H. Augustus Wilson gives an historical review of the various improvements and methods of procedure. He concludes from his personal experience that tendon transplantation, alone or combined with arthrodesis or other bone operations, offers prospects of materially adding to the comfort, convenience, and usefulness of a very large class of patients otherwise more or less dependent upon forms of mechanical apparatus. The frequently observed improvement in the action of muscles that previous to operation gave evidence of being paralyzed or atrophied from disuse, shows the capabilities of restoration when the offending abnormalities have been removed. It is impossible to estimate properly what the future development in a given case will be. The cooperative, intelligent care of the patient must be depended upon in securing the best permanent results. Muscles cannot develop when they are used to excess or are under constant strain. The atrophy from disuse, whether caused by tension or relaxation, often presents all of the appearances of paralysis. The avoidance of overstrain upon incapable muscles is often demanded, so that the minimum muscle force may accomplish the maximum of action. The after-treatment is fully as important as the surgical procedure, and must be given prolonged consideration in order to accomplish the best ultimate results. Arthrodesis alone possesses advantages in cases incapable of benefit from tendon transplantation. Various forms of osteotomy, osteoclasis, and other bone operations are available for the removal of deformity and for the prevention of undue strain upon the soft parts around a joint.

Enterostomy.—J. W. Long holds that the following important measures are accomplished by enterostomy: (1) Drainage of gas and feces from the intestines. (2) Relief of distention, pain, vomiting, and toxemia in mechanical obstruction. (3) Depletion of the inflamed bowel and peritoneum in septic conditions; the intestinal paralysis and sepsis are also overcome. (4) Protection to the peritoneum, as in typhoid perforation. (5) Nourishment to the patient by making an artificial mouth. The author considers the subject under these heads, and concludes enterostomy is always a life-saving measure, never an operation of choice. It is never indicated when a more ideal surgical procedure is feasible. In the hands of an experienced,

carefully trained abdominal surgeon, capable of dealing with grave emergencies, an enterostomy is rarely resorted to; but the better the surgeon the more quickly will he adopt any measure that will rescue his patient. Every abdominal surgeon finds cases in which only an enterostomy can with propriety be done. When an enterostomy is indicated, to hesitate is to lose the patient; therefore operation should be done promptly, dexterously, and with celerity. Dr. Long reports eight cases occurring in his own practice, with five recoveries.

Journal of the American Medical Association, April 8, 1905.

Ocean Bathing.—Philip Marvel calls attention to the effects of ocean bathing. Sea water is really a mineral water containing large quantities of salts in solution. He calls attention also to the effects of temperature; to the depression of the system due to long exposure in cold water, showing itself by a drop of from one to two degrees of body temperature and in lessening of the pulse rate from fifteen to twenty beats. If after a bath there is a general glow of the surface, succeeded by a pleasing warmth internally and accompanied by a sense of general invigoration, the effect is salutary. If, on the other hand, there is chilliness, depression, and languor, the reverse is the case. In his opinion, ocean bathing, as carried on in the Atlantic coast resorts, does more harm than good, and physicians should warn patients of the dangers of too long immersions and of exposure in wet clothes on the sand. The practice of promenading the beach in scanty and wet clothing after a long exposure in the surf is to be condemned. An important feature in sea bathing is the impact of the waves on the body, and to this may be added the thermic stimulation of the cold, the chemical irritation of the salt, and the mechanical effect of the forced activity, all producing a combination of the stimulating influence of a brine bath at low temperature with the effect of a stimulating hydrotherapeutic procedure. These effects are admirable for stimulating functional activity in weakened conditions in which normal metabolism is inhibited, or in which a condition of perverted nutrition exists, as in some functional disturbances of long standing. Sea bathing is contraindicated, however, wherever there is weakening or loss of elasticity of the arteries, organic heart disease, recent rheumatism, cholelithiasis, acute gastrointestinal or febrile disease, or in any condition where the normal resistance is so reduced that it is necessary to guard the patient's forces.

The Elimination of Typhoid.—A. Robin holds that, while bacteriological proof is lacking in the chain of evidence connecting typhoid fever with a polluted water supply, there is yet abundant clinical and epidemiological evidence of this relation. It is a striking fact, however, that even artesian well water seems to be among the possibly polluted sources. That the infection is avoidable is amply shown by European and American experience. He goes at length into the prophylaxis of typhoid fever, and shows that domestic methods, except boiling water, which is often only sporadically employed, are generally ineffective. Even the best domestic filters require frequent cleansing and sterilizing to keep them in good condition. The use of unboiled water to cleanse foods that are eaten raw, and a polluted milk supply are also to be held accountable for infection. Municipal prophylaxis also may be defective, especially if mechanical filters are employed, and he illustrates this by a comparison of the typhoid death rates of Wilmington, Del., which is thus supplied, and that of Lawrence, Mass., where the better plan of slow sand filtration is in use. There should also be laws preventing the discharge of raw sewage into streams which supply the drinking water of towns. For the purification of sewage he believes the septic tank method promises the best results.

Variola.—W. T. Howard, Jr., has followed up the study of the organism found by Councilman, McGrath, Brinckerhoff, and Tyzzer in variola and its life cycle. He finds that these bodies in their various stages are constantly present in the skin lesions of vaccinia and variola, and gives the technic of their study. Zenker's fluid is the only fixative that is satisfactory, and it is important that the section should be made so as to include the whole thickness of the skin. Mallory's is the best methylene blue eosin stain for these bodies, but other methods, such as that of Borrel and Weigert's fibrin stain, preceded by carmin, may be used. The bodies stain brilliantly, and with a good light and an oil immersion lens, should be easily recognized in properly prepared specimens. In the later stages of the disorder the Borrel stain is best. A second cytoplasmic stage recognized by Howard and Perkins is found only in well-established variola vesicles, never in vaccinia, so far as known. The other stages are the intranuclear ones already described by Calkins, with the exception of one which was not found by Howard, and which appears in the later stages of the eruption. It is useless to look for cytoplasmic forms (excepting in local autoinfection) in late lesions, or for the intranuclear forms in early ones The importance of these findings is in the service they may render in the early diagnosis of variola and vaccinia. Howard believes that this can be made in doubtful cases, with the result of cutting short various epidemics in their beginnings.

Tropical Amebiasis.—W. E. Musgrave gives the results of his experience with tropical amebic dysentery in Manila, where it causes more than 50 per cent. of the invalidism of public, and especially of civil, employes. In the military service there is a smaller percentage on account of the stricter regulations and the medical oversight. The use of cold drinks, and especially of ices containing encysted amebæ, is specially dangerous. Fresh vegetables are responsible for some cases, and others come from lack of cleanliness of the hands. He condemns the tendency to routine treatment. Acute cases should be kept in bed, on fluid diet, pain being controlled by opiates or by local applications; calomel and salines and enemas are useful. After the acute symptoms subside, strict confinement is no longer required, because the patient usually can be treated at home, and can have the benefit of carefully directed moderate exercise. Musgrave advises a liberal diet, except where there is disturbance of the stomach and the small intestines. While change of climate is desirable, especially in old, obstinate, and emaciated cases, it should be preceded and followed by careful local treatment. He thinks that the routine use of bismuth has worked harm, at least in a negative way, by interfering with the effects of other drugs. Ipecac, as sometimes prescribed, is apt to be dangerous, but in small doses it may act beneficially. Salines should be used with caution for catharsis only. Musgrave favors the hydrochloric acid and pepsin combinations. Strychnia, while a valuable general tonic, is too stimulating to the bowels to be used simultaneously with enemas. Local treatment is important, and he goes at length into the directions for the administration of injections. The various salts of quinine have been the most satisfactory agents in this method of treatment. There is little choice, apparently, between the different salts, but the solution should be an acid one and of a strength from 1-150Q to 1-750. In concluding his paper Musgrave notices at some length appendiceal amebiasis. Appendicitis may occur, either independently of the amebic affection or as a continuation, by contiguity, of the structures. In a minority of these latter cases operation may be performed, but more frequently the surgeon will find a gangrenous cecum and will increase his mortality rate. Generally the symptoms re due to irritative involvement of the cecum, without amebic involvement of the appendix.

The Lancet, April 1, 1905.

A Soluble Button for Intestinal Anastomosis.—P. Patterson has discovered this desirable medium in a combination of gelatine with chrome alum. Ten grains of chrome alum are dissolved in one ounce of cold water. Moulds are then prepared—lined with a layer of strong muslin and filled with a strong watery solution of gelatine. The fibrous mould-lining becomes saturated with the gelatine and incorporated with the outer portion of the gelatine button, giving additional strength, while diminishing the tendency to brittleness. When the gelatine has set, the casts are removed from the moulds and placed in the alum solution (one button to each ounce of the solution) for twelve hours. They are then kept in 50 per cent. alcohol until required for use. A button three-quarters of an inch in diameter resists solution for about five to seven days when placed in the bowel. The buttons are used in the same general way as the Murphy button. Thick hydraulic dental cement may be used, if necessary, to firmly approximate the male and female halves.

Pericolitis Sinistra.—Under this title H. D. Rolleston groups the following conditions: (1) Local peritonitis of comparatively slight intensity around the descending colon or the sigmoid flexure; (2) a local abscess in connection with the descending colon which may eventually burst into the general peritoneal cavity and set up (3) general peritonitis. The clinical manifestations are as follows: After constipation of some duration the patient experiences pain in the left iliac fossa, usually has a somewhat raised temperature, and may vomit. On palpation there are deep tenderness, muscular resistance, and a more or less cylindrical tumor palpable in the left iliac fossa, features which suggest appendicitis on the left side. Leucocytosis and indicanuria have been noted in some instances. Several illustrative clinical histories are given.

The Vibrating Sensation in Affections of the Nervous System and in Diabetes.—R. T. Williamson notes that when the foot of a vibrating tuning fork is placed over subcutaneous bony prominences or surfaces in certain parts of the body a peculiar vibrating sensation is felt. If, for example, the foot of a vibrating tuning fork be placed firmly in contact with the ulnar side of the wrist, just at the prominence caused by the styloid process of the ulna,

a peculiar vibrating or trembling sensation is felt at the region named, and in many healthy persons this sensation is felt throughout the whole length of the ulna. A similar sensation is felt when the foot of a vibrating tuning fork is placed over the subcutaneous processes or surfaces of many other bones. The author uses a fork six inches long, and finds the following three places convenient for examination: The styloid process of the ulna, the internal malleolus, and the inner surface of the middle tibial region. From examination of a considerable number of healthy and diseased individuals, he comes to the following conclusions: (1) In the normal condition the vibratory sensation, tested in the manner described, is probably always present at the three points mentioned. (2) In early tabes it may be lost in the legs before impairment of other forms of sensation occurs and before ataxia or Rhomberg's sign can be detected. (3) In certain cases of spastic paraplegia it may be lost in the legs, when other forms of sensation are not affected. (4) In some cases of diabetes mellitus and chronic glycosuria it is lost when sensation in other respects is normal. (5) From these facts it is evident that sensation cannot be declared to be normal until the vibrating sensation has been tested. Though the loss of the vibrating sensation is a symptom of considerable interest, it is at present too early to say what its diagnostic value will be in the future.

The Growth of Cancer.—E. F. Bashford declares that the problems of cancer are essentially the same throughout the entire vertebrate creation. The "age of incidence" is relatively the same in all, when we take into account the normal duration of life in the different classes of animals. It takes so long to study the various stages of processes of cancer growth in man that it has been hoped that we might obtain important information from the study of cancer growth in short-lived animals. Such growth is essentially different from a simple process of infection. The experimental propagation of a malignant new growth means simply the continued proliferation of the cells of one animal in another animal. The parenchyma cells of the neoplasms arising at the new sites are the direct genealogical descendants of those introduced, and are not provided by the host. In experimental propagation of cancer the elements of the soil play the insignificant part of subserving the needs of the tumor. The main ideas of the author are embraced in the following conclusions: (1) Cancer is identical in all vertebrates, and in growing accommodates itself in a striking manner to the time limitations imposed by the compass of life in different animals. (2) Underfavorable experimental conditions the growth of cancer is undefined, of enormous, and, so far as we can judge, limitless amount. (3) Artificially propagated cancer (2) Under favorable experimental conditions the growth of sporadic tumors. (4) The growth of artificially propagated cancer is due to the continued proliferation of the parenchyma cells. We have confirmed this conclusion, originally advanced by Jensen, on his own tumor and on four other different carcinomata. (5) The artificially propagated parenchyma makes the reaction of the host subserve its own needs. (6) Artificially propagated tumors cause no symptoms in the organism to which they have been added. (7) The power of differentiation is definitely in one direction only, even three and a half years after separation from the original host. (8) The number of chromosomes constant for the healthy body tissues is retained, notwithstanding the recurring reduction of this number to the exact half.

British Medical Journal, April 1, 1905.

The Diagnostic and Prognostic Value of the Leucopenia of Cachexial Fever and Kala-Azar, and Its Treatment by Quinine and Bone Marrow.—Leonard Rogers presents the following conclusions: A very marked decrease in the leucocytes is always found in uncomplicated cases of cachexial fever, and when they number below 2,000 per c.cm. this is almost diagnostic of the disease, but may rarely occur in true malarial cachexia. In cachexial fever the white corpuscles are reduced to a greater degree than the red, so that the ratio falls below 1 to 1,000 in all uncomplicated progressive cases. This is rarely so in true malarial cachexia, while a reduction in the ratio to below 1 to 1,500 appears to be quite diagnostic of cachexial from other Indian fevers. The most marked degrees of reduction of the leucocytes, and especially of the polynuclears, is of bad prognostic import, and vice versa. Red marrow tabloids are of great value in increasing the leucocytes, and this increase may take place during the continuance for months of intermittent fever, and be then followed by cessation of the fever and complete recovery. High remittent fever is accompanied by progressive deterioration of the blood and general condition, but it may be often to a large extent reduced to the less injurious intermittent form by continued large doses of quinine, combined with red marrow. The best results yet reported have been obtained by those who carry out vigorous quinine treatment.

Enterectomy at Twelve Hours of Age; Recovery.—A. E. Kennedy believes that this case which he reports must be the earliest of the kind on record. The patient was a child twelve hours old. Meconium was coming away from the umbilical cord. The writer found a fistula the size of a crow's quill about one inch from the umbilical aperture in the side of the cord. He slit the cord longitudinally—not using an anesthetic—thus exposing a blind finger-like process of intestine, with the fistula in its side. When drawn out of the umbilical aperture it proved to be about two inches long and to come from the cecum. The intestine on either side of it was so narrow that the writer did not think it capable of maintaining the alimentary passage. He excised the narrowed intestine and joined the large to the small intestine by lateral anastomosis, closing the end of the large intestine. The intestine was returned into the abdomen and the umbilical aperture closed after removal of the umbilical cord. The child made a good recovery. The newly-born infant bears the handling of the intestine well, as far as can be told, and apparently does not feel pain, for this infant quietly sucked a sugared teat while its intestine was being stitched.

Chronic Constipation and Its Medical and Surgical Treatment.—W. Arbuthnot Lane states that the condition of constipation often dates from a very early period, when, owing to the unsuitable feeding of the child, the intestines, particularly the large bowel, are distended with gas. The cecum and ascending colon appear to suffer most severely, since this part of the bowel is hung up at the hepatic flexure, which is made more acute by the distension and consequent elongation of the transverse colon in a downward direction. The large bowel becomes more or less inflamed, and even a distinct peritonitis may be reproduced. The inflammation of the cecum and ascending colon produces an adhesive process between the outer wall of the bowel and the peritoneum, with which it comes in contact. These adhesive processes develop also about the hepatic flexure and at the splenic flexure. By these adhesions the bowel is more or less fixed, and it is thus hindered from normally performing its functions. The muscle wall wastes as the free action is limited. The presence of the inflamed large bowel in the true pelvis readily interferes with the functioning of the ovary and Fallopian tube. Thus constipation would appear to play an important part in the sterility so common among women. The small intestines become progressively dilated from below upwards by their dammed-back contents. The muscle wall is thinned and the capacity of the intestine for performing drainage efficiently is diminished. The stomach itself may become disabled. In a large part of these cases the kidneys are mobile. A conspicuous clinical symptom is a fullness and tenderness in the region of the cecum. There is often pain along the course of the sigmoid. The appendix is sometimes removed for the amelioration of these conditions, with only the temporary relief afforded by the prolonged assumption of the resting posture favorable to the emptying of the cesspool, and by the care that the bowels receive during convalescence. In certain cases the patient refers all pain to the epigastrium or to the umbilical region, and the many symptoms of "indigestion" may be present in an aggravated form. After a certain period of time the patients lose fat. This is the best indication that can be given that the patient is going downhill. The writer does not deal with any other form of treatment than the operative, for he assumes that everything short of operative interference has been tried. The problem generally presents itself as to whether an attempt should be made to liberate the constriction by the division of bands or adhesions, or whether it would be better to establish direct continuity between the lower end of the ileum and the termination of the large bowel. In men, the former is apt to give relief, while the latter is more successful in the case of women. The writer urges the importance of early operation, since the results vary inversely with the length of time during which the constipation has existed and with the mechanical changes resulting from such constipation.

The Experimental Transmission of Mediterranean Fever.—Edward H. Ross and G. Murray Levick give the methods and results of various experiments which they have tried in relation to the transmission of Mediterranean fever. Non-immunes have nursed cases of the fever, taking no special pains to avoid contracting the disease. They have also slept in the bedclothes used by a patient. The results were negative. The urine of a case of fever was mixed with dust and the paste allowed to dry. It was then powdered and inhaled, sniffed up the nostrils and swallowed by non-immunes. The disease was not conveyed in this manner. The urine of a fever case in the sixth week of the disease was mixed with drinking water, and two non-immunes drank the mixture. This did not cause any untoward results. Experiments with mosquitos did not result in the transmission of the disease. The mos-

quitoes were infected from cases in different stages of the disease and allowed to bite the non-immunes. All of the experiments so far have failed to produce the disease, but the investigators declare their intention to persevere with their researches until they find the true nature of the transmission of the Mediterranean fever and the method of its prevention.

Berliner klinische Wochenschrift, March 20, 1905.

The Morphology of Carcinoma and the Parasitic Theory.—J. Orth, after a lengthy exposition of the theoretical grounds which make it unlikely that carcinoma is of parasitic origin, sums up the objections to the present status of this theory as follows: The essential feature of all cancers, primary and secondary, is the cancer cell; without the cancer cell, no cancer metastases. In order to explain the occurrence of metastatic deposits it is not necessary to presuppose the existence of parasites, for cancer cells capable of proliferating suffice for this. It is not possible to establish an analogy between the metastases of malignant growths and those of suppurative processes, tuberculosis, etc., and the question of analogy cannot be used as an argument in favor of the parasitic nature of carcinoma. The cases in which transplantation of cancer to another individual has succeeded can be explained without calling in the aid of the parasitic theory, through the assumption of direct transport, the cancer cells simply giving rise to metastases in another body. The various parasites that have so far been described are still entirely inadequate to form a basis for scientific speculation, or, in other words, the parasitic theory is still all in the air.

Rectal Gonorrhea in Infantile Vulvovaginitis.—Flügel found that of the women patients under treatment for gonorrhea in the City Hospital of Frankfort, about one-third were also suffering from rectal infection. In extending his investigations to the children in the wards he found twenty cases of gonorrhea of the rectum in fifty-six patients. The presence of the gonococcus was established by passing a wire loop into the anus, and it is noted that in many cases the examination had to be repeated a number of times before a positive result was obtained. Under the circumstances, it seems most likely that infection takes place through the flow of discharge from the vagina, and the author suggests as a prophylactic measure that a pad of gauze suitably supported be kept in constant apposition with the vulva. Treatment consisted in the use of suppositories and irrigations of silver nitrate, and of icthyol suppositories. The gonococci usually disappeared from the rectum much earlier than from the vagina, and the rectal symptoms were never very severe.

Münchener medizinische Wochenschrift, March 21, 1905.

The Treatment of Epidemic Cerebrospinal Meningitis.—Lenhartz has observed forty-five cases of this disease during the past ten years, in forty of which the diplococcus intracellularis of Weichselbaum could be identified. He accordingly concludes that this organism is the exclusive inciting agent of the malady. The object of his communication is principally to direct attention to the therapeutic value of lumbar puncture in these cases. The histories of several cases are reproduced in order to demonstrate the improvement in objective and subjective symptoms, particularly the relief of the headache, following the diminution in intracerebral pressure. The operation in many cases was frequently repeated, in one instance fifteen punctures being made and a total of 400 c.c. of fluid removed. The author recommends making the puncture exactly in the middle line between the spinous processes of the vertebræ, at the level of the iliac crests. It is of great assistance to have the spine curved forward as much as possible by bringing the thighs up against the abdomen. Not more than 30-50 c.c. of fluid should be drawn off at one time in the average case.

The Dilatation of Cicatricial Stenoses of the Esophagus Through the Esophagoscope.—Reizenstein, who is an enthusiastic manipulator of the instrument, reports several cases in which the esophagoscope was found of great service in the treatment of cicatricial contractures, and summarizes his views as follows: In cases of this sort, if the stricture is not permeable by the ordinary instrumentation, before resorting to operative procedures the attempt should be made to locate the lumen of the constricted zone in the esophagoscope and to introduce filiform bougies under the guidance of the eye. If this is possible, the effort should be made to secure dilatation by introducing laminaria pegs, stretched rubber tubes, or flexible metal bougies. If unsuccessful, a gastrostomy should be done and retrograde dilatation, or dilatation following the shot and string method, be resorted to. If the condition of the patient is such as to prevent immediate nourishment, gastrostomy should be postponed. If all attempts to pass the stricture fail, external or combined esophagotomy is indicated.

Forensic Proof of Death by Drowning.—Revenstorf draws the following conclusions from a study of this question. Hemolysis of cadaveric blood in the first days after death is neither the result of physical changes nor of autolysis, but is due to bacterial activity, *i.e.* putrefaction, and is one of the earliest macroscopic signs of commencing putrefaction. Through this agency the portal blood is decomposed to the greatest degree, that of the right heart and its tributaries to a less extent, and that of the left heart and of the arterial system least of all. If anisotonic fluids entering the air passages come into intimate contact with the blood corpuscles, hemolysis results. Hemolysis following death by drowning differs from that of ordinary death in the fact that the serum of the left heart shows a higher grade of hemolytic decomposition than that of the right side. Pulmonary tissue juices, pleural transudates and pericardial fluid that contain no dissolved hemoglobin are free from admixture of the drowning fluid. Watery edema always shows hemoglobin serum, while colorless serum indicates true pulmonary edema. The hemolysis of drowning is an indication of this form of death which in accuracy surpasses the other methods of demonstrating the presence in the blood of extraneous fluid. The absence of diffusion of the coloring matter of the portal blood, together with hemolysis of drowning, in the heart blood, is evidence that the foreign fluid diffused itself into the cardiac contents only after cessation of circulatory activity.

Deutsche medizinische Wochenschrift, March 9, 1905.

The Treatment of General Peritonitis.—Barth considers that gastric lavage is of the greatest value in treating the tympanites and intestinal atony following operations for this condition. Even before vomiting has set in, the use of the stomach tube will often reveal the course events are about to take by bringing up from the stomach enormous amounts of fluid regurgitated from the intestine. In addition to lavage the author has found enterostomy a valuable measure in promoting the return of peristaltic activity. Ordinarily the little operation can be done without anesthesia. The operation wound usually gives access to one of the dilated loops of gut, which may or may not, according to circumstances, be stitched to the parietal peritoneum. The intestine is then punctured with a fine trocar to which a length of rubber tubing is attached, and which is retained in position by a suitable dressing. On removal of the trocar the puncture in the intestinal wall closes without any necessity for suturing. In case it is not practicable to use the operation wound for this purpose a small incision is made in either side of the abdomen. The histories of eleven cases in which this plan of treatment was used are abtracted and show that in seven the procedure apparently contributed to the recovery of the patient.

Hyoscine-Morphine Narcosis.—Dirk has employed this method in two hundred and sixty patients of all ages, the number including one hundred and eighty-eight laparotomies. The usual course of procedure was to give the patient two hypodermic injections, amounting together to 1mg. of scopolamine hydrobromate, and 2.5 cg. of morphine, two hours and one hour, before the operation. The author expresses himself as very much pleased with the method, which always greatly reduces the amount of general anasthesia necessary, and frequently renders it possible to dispense with all further narcosis. The patients after the second injection become apathetic and unresponsive, so that usually they have no recollection of what has happened after this time until they awaken from the deep sleep lasting seven or eight hours, which usually follows the termination of the operation. In this way they are brought comfortably through the first period of postoperative pain, and the usual nausea and vomiting are entirely eliminated. Three cases of death occurring five to seven hours after the operation are reported, but these were all in persons from sixty-nine to seventy-six years old, under conditions which render it doubtful whether the narcotics were at fault or not. The author believes that for hospital work, where the patient can be under trained supervision both before and after the operation, the method is very advantageous, and that it deprives major operations of their chief terrors for the patient, viz., the disagreeable sensations accompanying the administration of the anesthetic and the postoperative nausea. In the discussion that followed, Israels reported on 332 operations performed under the influence of the combined narcotics, and also expressed himself as favorably impressed by the method. He had one patient die on the table and two others some days after the operation under circumstances which render it possible that the drugs contributed to the fatal ending.

The Value of the Koplik Spots in the Diagnosis of Measles.—Brüning shows that although the vast majority of reports indicate that the Koplik enanthem is visible in practically all cases of measles, especially before the appearance of the rash, still a few observers have published less confirmatory statistics. A study of one hundred cases

of measles seen during a recent epidemic of the exanthemata in Leipsic leads him to ascribe the greatest value to the sign, both from a diagnostic and differential point of view. The spots were never found in cases of rubeola, scarlatina, or serum rashes, whereas they are to be considered as invariably present in measles, and must be valued as an important differential aid in diagnosticating the exanthemata both in private and in hospital practice.

French and Italian Journals.

Treatment of Typhoid Fever by the Tincture of Iodine.—For several years Raynaud has systematically treated all of his typhoid fever patients by the internal administration of the tincture of iodine. The results of this treatment have been very striking, for not only have all of these patients recovered, but in 90 per cent. of the cases, the duration of the fever has not been over from twelve to fourteen days. In the beginning of the illness calomel is given. Its dose is in inverse ratio to the temperature, for the action of this drug is more energetic in hyperthermia. There is no other medication given on the day that calomel is administered. On the next day and the three following days, the tincture of iodine, from twenty to twenty-five drops in a potion of 150 c.c. is given in the twenty-four hours. All of the vehicles for this drug are not equally convenient. The iodine evaporates too rapidly in sweetened or alcoholic solutions. Distilled water gives a more stable solution, especially if a trace of potassium iodide is added. The mixture is made up as follows: Tincture of iodine, 20 to 25 drops; potassium iodide, 0.01 gram; water, 150 c.c. On the sixth day the calomel is given again. On the seventh day and on the following days the iodine is administered. The only medicament besides iodine to which Raynaud has recourse is the sulphate of strychnine, in cases in which there is great depression or in which the heart is weak. This drug is given in the dose of 2 milligrammes a day. By twelve or fourteen days after the beginning of the treatment, the fever is nearly always terminated, and the patient has begun to convalesce.—*Revue Française de Médecine et de Chirurgie,* March 27, 1905.

Extirpation of the Lacrymal Sac and Canal.—Basso believes in the extirpation of the sac. He has practised it in cases of simple dacryocystitis without lacrymal tumor, in dacryocystitis with lacrymal tumor, in dacryocystitis with tumor and fistula, in stenosis of the nasal orifice, in mucocele and empyema of the sac. The writer does not recommend the opening of the sac. The macroscopical and microscopical examination of the specimens taken from various cases, show that in simple dacryocystitis without lacrymal tumor and without purulent secretion with simple epiphora, there is ordinary diffuse infiltration of the sac and of the canal with polypoid vegetation. In dacryocystitis with dilatation of the sac, there exists an organic stenosis of the canal. The osseous and membranous canals are no longer in contact.—*Recueil d'Ophthalmologie,* March, 1905.

Differentiation of the Fusiform Bacillus from the Spirillum Sputigenum.—Certain authorities have suggested the hypothesis that the fusiform bacillus, the pathogenic agent of Vincent's agina, was the same organism as the spirillum sputigenum. Vincent has demonstrated that the fusiform bacillus never assumes the spiral form, neither in exudates nor in cultures. There are besides this other fundamental differences between these organisms. The dimensions of the fusiform bacillus are from 6 to 10 micra in length by 1 to 1.5 micra in width. The spirillum sputigenum measures from 1 to 2 micra in length by 0.4 micra in width. The fusiform bacillus is spindle shaped, or like an elongated lozenge, and its protoplasm often shows irregular vacuoles, as if it were full of holes. The spirillum sputigenum is, on the contrary, identical in form, appearance, dimension, mobility, and color characteristics, with the vibrio of cholera. It is a comma bacillus. The fusiform bacillus can be cultivated, the spirillum sputigenum cannot be. The former is slightly mobile in exudates, but immobile in cultures. The second has great mobility. These organisms could not possibly be identical.—*Gazette des Hôpitaux Civils et Militaires, March* 21, 1905.

Iodized Gelatin in the Treatment of Basedow's Disease.—Valerio Lusini reports the case of a girl of 20 years, who was affected by an acute case of Basedow's disease. The thyroid gland had been increasing in size for about three months before she came under treatment. She had no other disturbances except frequent cardiac palpitations. The thyroid became much enlarged, was hard, not painful on pressure, and there was bilateral exophthalmos. The area of diffusion of the heart beat was much enlarged, pulsations 120-130 per minute, increased to 160 by excitement. Iodide of soda in large doses and iodide of potash were given, with external applications of iodine to the gland, with no beneficial results. She was then put on iodogelatin by the mouth, 100 grammes of the preparation containing 2 grammes of iodine. After twenty days she was so much improved as to be willing to have the iodogelatin used hypodermically. A course of three weeks of injections of 5 c.c. of the iodated gelatin, containing 0.10 grammes of iodine was administered, a week of rest given, and then the course repeated. The result was a complete reduction of the enlargement of the gland; the heart-symptoms passed away, the pulse being reduced to 78, and only a small amount of exophthalmos remained. After three months the patient remains completely well.—*Rivista Critica di Clinica Medica,* March 11, 1905.

Action of Alkalies on the Poison of Tetanus.—Giulio Cerri gives us the results of his experiments on guinea pigs with injections of tetanus toxin mixed with hydrate of soda. He first determined the amount of toxin necessary to kill a pig of 400-450 grammes in 24 hours. He then injected twice that amount of toxin mixed with a solution of sodium hydrate. His conclusions are as follows: (1) Caustic soda prevents the toxic action of tetanus poison. (2) Three milligrammes of soda is sufficient to neutralize doses three and four times larger than the lethal dose for guinea pigs. (3) The loss of activity of the toxin through the use of the soda is not due to the prevention of its absorption, nor to a chemical combination with the toxin, but to an effect on the direct action of the poison.—*Lo Sperimentale,* January-February, 1905.

Elimination of the Bile by Man After the Ingestion of Proteids and Fats.—Francesco Randone experimented on a patient who had a permanent bilary fistula, feeding him with different food substances and then watching the flow of bile. He gives us the following conclusions: (1) The ingestion of food in man is followed by a marked elimination of bile, which begins soon after ingestion and reaches its maximum at the end of three hours. (2) The ingestion of proteids does not modify the relations existing between the elimination of bile and that of urea in the urine. (3) The ingestion of fats does increase, but less than do proteids, the elimination of bile; this does not occur immediately after ingestion, but about the end of one hour, and is greatest after a quarter of an hour from the beginning. (4) The ingestion of fats changes the relations of urea to bile. (5) The results of Barbera, obtained by experiments on dogs, are confirmed by these on man.—*Il Policlinico.*

Gastric Tetany.—According to Pol Gargaud, tetany is observed in the adult in the most diverse affections of the digestive tract. Various authorities have noted its existence in typhoid convalescence; again, following dysentery, and following cholera. Many have reported its existence in cases of diarrhea of every kind. In most of the cases which have been published up to this time, tetany has been preceded—at varying intervals—by more or less violent or repeated attacks of vomiting. In a case of Gargaud's nothing of this kind occurred, the tetany developing like an absolutely primary affection. The patient, a man of forty-nine years, entered the hospital on July 13, suffering with rigidity at the nape of the neck. The whole picture of tetany developed. He grew weaker gradually. On August 14, for the first time, he vomited dark blood. Death took place the same evening. At autopsy, an annular scirrhus cancer of the pylorus was found. There had been no functional trouble before the hematemesis to draw attention to the stomach. Renvers has reported a case in which tetanus developed suddenly in a man who appeared to be in good health. At autopsy ulcer of the duodenum, pyloric stenosis, and hypertrophy of the gastric musculature were discovered. In cases of tetany, even in the absence of any appreciable functional trouble, careful examination of the stomach for a possible gastric origin, should be made.—*Revue Française de Médecine et de Chirurgie*

The Value of the Electric Potential in Electrodiagnosis.—A. G. Gramegnau discusses the best method of measuring electric excitability, and has experimented on patients to test this matter. He concludes that voltage is not the precise exponent of excitability, since it is subject to all the variations of the body resistance during an examination; milliampères tend to increase, while volts tend to diminish. The electric excitability of nerve and muscle in man, expressed in milliampères is the same whether used with low or high potential; intensity is the best measure of nervous and muscular excitability. The best methods for an electric examination are those which render the body resistance least. These are equal electrodes; the indifferent electrode placed on the palm of the hand or sole of the foot; fixed electrodes, with temperature and pressure maintained the same, and an interruptor in the circuit; instantaneous closure of the circuit; an aperiodic galvanometer, and the use of relatively high initial potential.—*Rivista Critica di Clinica Medica*

Book Reviews.

The Medical Examination for Life Insurance and Its Associated Clinical Methods. With Chapters on the Insurance of Substandard Lives and Accident Insurance. By Charles Lyman Greene, M.D., St. Paul. Professor of the Theory and Practice of Medicine in the University of Minnesota, Member of the Association of American Physicians, American Medical Association, ex-President of the National Association of Life Insurance Examining Surgeons, etc. Second Edition, Revised and Enlarged, with 99 Illustrations. Philadelphia: P. Blakiston's Son & Company, 1905.

Although published only a little over four years ago, this book has been out of print for two years, a fact that speaks eloquently for the widespread recognition of its utility. In its present form the volume has undergone such radical revision that it has become almost a new work, for much of the old matter has been rewritten and a great deal of new material incorporated. Among the additions are a report of the investigations of the Actuarial Society of America, many graphic statistical plates, and details concerning the rules governing selection, and bearing on some of the more important diseases from an insurance standpoint, such as diseases of the heart, appendicitis, tuberculosis, etc. The section on physical signs in diseases of the chest forms an admirably written and illustrated dissertation on this subject, which should prove interesting and instructive to all practitioners, whether engaged in insurance work or not. Indeed, every section of the volume contains much information likely to be of general utility, and certainly for the guidance of insurance examiners it is a very good manual.

Studies in General Physiology. By Jacques Loeb, formerly of the Department of Physiology, University of Chicago, now Professor of Physiology in the University of California. The Decennial Publications, Second Series, Volume XV, Parts I and II. Chicago: The University of Chicago Press, 1905.

It is only necessary to mention the titles of a few of the thirty-eight papers contained in this collection, all of which are the sole work of the author, in order to convey an idea of the extraordinary interest attaching to their perusal. Some of these are: The Artificial Transformation of Positively Heliotropic Animals Into Negatively Heliotropic and *vice versa;* On a Simple Method of Producing from One Egg Two or More Embryos, Which Are Grown Together; On the Limits of Divisibility of Living Matter; The Influence of Light on the Development of Organs in Animals; The Physiological Effects of Ions; On the Nature of the Process of Fertilization and the Artificial Production of Normal Larvæ (Plutei) from the Unfertilized Eggs of the Sea Urchin; Maturation, Natural Death, and the Prolongation of the Life of Unfertilized Starfish Eggs (Asterias Forbesii), and Their Significance for the Theory of Fertilization. It is impossible in a notice of so extensive a series of investigations, which, although correlated by a dominant motive, still embrace widely differing fields of observation, to do more than indicate the general trend of the author's work. The fundamental object was to show that vital phenomena are subject to certain influences, which it is in our power to control, and in approaching this problem the author has studied the agencies governing the direction of the motions of animals, the phenomena of regeneration and of heteromorphosis, and, finally, the far-reaching question of fertilization.

The Naked Eye Anatomy of the Human Teeth. By Thos. E. Constant. Bristol: John Wright & Company, 1905.

This book presents a very comprehensive account of the anatomy of the teeth and of the muscles and other structures which come into relation with them. It is noteworthy for a series of most excellent photographic plates, which alone make the book of considerable value. Among them are a number depicting the changes in the dental succession, which have been made from dissections of the skulls of infants at various ages. These are particularly interesting and instructive for any one studying the dentition of children.

A Treatise on Urological and Venereal Diseases. By B. G. Carleton, M.D. Philadelphia: Boericke & Tafel, 1905.

The author has endeavored to give a thorough presentation of the approved essentials and principles involved in the pathology, diagnosis, and treatment of urological and venereal diseases. It is tinctured to some extent by his personal experiences and conclusions, and it is also made distinctive by the space devoted to the application of homeopathic principles for the cure of disease. The book is essentially a compend, most of the material being derived with "grateful acknowledgment" from sources other than homeopathic. The specific remedies of the latter school are especially recommended and a variety of proprietary drugs are also prominently mentioned. The illustrations are numerous and derived from many sources, but as a rule are very poorly executed.

The Old Family Doctor. By Henry C. Brainard, M.D. Cleveland: The Arthur H. Clark Company, 1905.

Another member of the profession has received the call to pronounce a eulogy on our old friend, the family doctor. And it is well that those of the present generation should not forget their prototype. His store of scientific medical knowledge may not have equaled that of his successor of the present day, but his grasp on human nature and his ability to dispense what we now call "unconscious therapeutics" makes his character not only an interesting study, but a worthy model in many respects. Within the brief limits of this little book are depicted comedy, tragedy, and melodrama, all of which afford a pleasant hour in the reading.

Bacteriology and Surgical Technique for Nurses. By Emily M. A. Stoney, Supt. of Training School, St. Anthony's Hospital, Rock Island, Ill. Second Edition, thoroughly revised and much enlarged by Frederick Griffith, M.D. Philadelphia, New York, and London: W. B. Saunders & Company, 1905.

This is a very practical book which presents the subjects stated in the title in a concise, yet sufficiently expanded, manner, that a nurse may gain much information as to the whys and the wherefores of the work she is called upon to do. The revised second edition contains some eighty new pages of text and many cuts, the added chapters including "Bandaging and Dressing," "Obstetric Nursing," "Hygiene and Personal Conduct of the Nurse." A valuable aid is a glossary, containing all of the terms and technical phrases commonly employed with which a nurse should be familiar. The work constitutes a practical book of reference for nurses in either private or hospital practice.

Die Physiologischen und Pathologischen Beziehungen der weiblichen Sexualorgane zum Tractus Intestinalis, und besonders zum Magen. Von Dr. Erwin Kehrer, Privatdocent an der Universität und Assistenzarzt an der Univ.-Frauenklinik in Heidelberg. Berlin: Verlag von S. Karger, 1905.

This monograph embodies the researches of Kehrer on the state of the stomach in menstruation, pregnancy, lactation, menopause, and various gynecological conditions. It is replete with practical deductions and clinical facts, and presents many new ideas worth considering. Space forbids a full analysis, but we should like to call attention especially to the detailed study of hyperemesis, of the dietetics of pregnant and parturient women, etc. Changes of motility of the stomach, according to the author, play a more prominent rôle in menstrual gravid, or puerperal digestive disturbances than actual changes in secretion. Yet a hypoacidity is often found (in three-fifths of the puerperal women). There has been a great deal too much talk of reflex gastric disorders in gynecological conditions. Often these disorders depend on totally different causes, the author found. In 42 per cent. of a series of cases with dyspeptic signs, the stomach contents were normal.

Important deductions are drawn by Kehrer in his study of cancer of the genital organs. He solemnly warns operators against removing ovarian cancers without examining the stomach contents for possible metastases, which he says are more frequent than has been supposed. This principle has already gained currency in cancer of the uterus, where operators should examine the bladder for cancerous involvement.

Elements of Applied Microscopy. A Text-Book for Beginners. By Charles-Edward Amory Winslow, Instructor in Industrial Microscopy and Sanitary Biology in the Massachusetts Institute of Technology. New York: John Wiley & Sons, 1905.

This little manual is intended as a laboratory guide in applied microscopy for students of chemistry, biology, and engineering, but will also serve as an elementary treatise on the technique and applications of microscopy for medical and pharmaceutical students. It contains a well-arranged and systematized series of lessons on the microscope, its manipulation, the mounting and preparation of specimens, micrometry, the camera lucida, and a series of short chapters upon the microscopy of foods, common drugs, textile fibers, and paper, as well as upon the uses of the microscope in medicine, hygiene, medical jurisprudence, chemistry, and mineralogy. Naturally the subjects are not treated from the viewpoint of the specialist, but from that of the student and beginner. The book is well put together, lucidly written, and usefully illustrated.

Society Reports.

THE NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held March 20, 1905.

DR. FRANCIS J. QUINLAN IN THE CHAIR.

Nomination of Officers for the Ensuing Year.—Nominations for officers, for member of the Executive Committee, for Fellows and Alternates of the State Association and member of the Nominating Committee of the District Branch were made.

A Plea for Local Anesthesia in the Radical Cure of Inguinal Hernia.—Dr. JOHN A. BODINE read this paper. His communication presented a personal study of 300 radical operations for the cure of inguinal hernia under local anesthesia. The patients numbered 284; 16 were cases of double rupture. There were 275 males and 9 females. The youngest was 15, the oldest 80 years. Ten were strangulated. The omentum was amputated in more or less quantity 12 times. The appendix was found with the contents of the sac three times, and in each instance was excised. Undescended testicle was found once and removed. The hospital detention was two weeks and the patients were away from work one week in addition. The amount of cocaine used in no case exceeded one-half grain. No wound suppurated and no patient died. "Nerve blocking" made possible a painless dissection for the radical cure of inguinal hernia. The anatomy of this region was so constructed in accessibility, regional restriction, paucity of blood vessels, and above all sensory nerve supply as to make the operation in question the most favorable in general surgery for local anesthesia. No nerve trunk or sizable blood vessel was encountered in the skin or subcutaneous fascia. Beneath the aponeurosis of the external oblique lay the three nerve trunks that presided over sensation in the entire field of work. Th inguinal branch of the ilioinguinal the hypogastric branch of the iliohypogastric and the genital branch of the genitocrural were the three nerve trunks in question. If all three were found and cocainized the operation afterward was totally devoid of pain. Their identification was not difficult. The first two named lay between the two oblique muscles directly under the incision. The genitocrural was usually found among the structures of the cord. The nerves were named in the order of their pain-bearing importance and in the order of constancy of anatomical position. He said that the mortality, in the hands of a clean and competent surgeon, of operations for inguinal hernia was practically the mortality of the anesthetic. It was an obvious proposition that a solution of cocaine injected intermittently into the circulation, amounting in all to one-half grain and occupying an hour in its introduction, was less dangerous than ether or chloroform carried to the full surgical narcosis for the same period of time. He believed fewer wounds would suppurate under local anesthesia because of the more gentle handling of the tissues. Danger to the line of deep sutures from nausea and vomiting was obviated, a very important point. Morphine was administered because of its calmative effect upon the nervous organization, a trustworthy preventative of certain psychical phenomena which sometimes was encountered. The amount and degree of pain suffered by the patients was purely relative and differed widely; great pain to one was slight pain to another. The pain endured was not in any case as disagreeable as the nausea following ether narcosis. The line of skin incision was infiltrated throughout its extent. Fat could not be edematized after the skin incision. The external oblique aponeurosis required no anesthesia. After the sac was opened and contents dealt with the Trendelenburg position was used to retain viscera within the cavity to avoid the pain caused by crowding a pad in the peritoneal cavity. Operation upon the female was easier than on the male, the round ligament being less sensitive than the cord. He believed that if the future transplantation of the cord was abandoned, the radical cure of inguinal hernia would be strictly one for local anesthesia.

Dr. W. L. RODMAN of Philadelphia said he had had but very little experience with local anesthesia in hernia work and limited its use now to operations upon strangulated hernia. He spoke of one case of large umbilical hernia, which had been strangulated nearly five days. A large amount of omentum was excised which the patient did not feel at all. The only part of the operation that gave pain was when the parietal peritoneum was pinched. No pain was encountered in handling the intestines. Dr. Rodman believed this to be one of the best fields for local anesthesia because the nerves were so readily found. He saw Dr. Bodine operate and was interested in noting the entire cessation of pain after the ilioinguinal nerve was "blocked." Most pain seemed to be in cutting through the fat. It was of interest to note the matter of indifference whether two or three nerves were blocked so long as the ilioinguinal was cocainized. He questioned the advisability of operating under local anesthesia upon nervous persons. Personally he believed the dangers of general anesthesia were nonexistent, or at least greatly overestimated. He had never seen a death from ether, and but one from chloroform after twenty years' experience. More was said about the dangers of general anesthesia than really existed. Local anesthesia would never be tolerated in young children, because of the element of fright. He was inclined to believe that cocaine anesthesia would always be of limited utility and would never take the place of general anesthesia in operative surgery.

Dr. R. H. M. DAWBARN said that he believed it was through the brilliant and able work of Dr. Bodine that the profession as a whole would be likely to adopt, with certain exceptions, the customary use of local anesthesia in the radical cure of inguinal hernia. Thousands of men now wearing trusses would be operated upon if they knew it could be done without the employment of general anesthesia. He referred to the statement of Dr. Henry O. Marcy of Boston some time ago that one man in every ten was ruptured; Dr. Dawbarn thought that one in every twenty would be nearer the truth at present. The operation, if thought advisable, on a child was very easy because adhesions were not encountered as in adults when the hernia had existed for some time. Again he thought it made a difference in the ease of work whether the sac was distended or empty; under general anesthesia one often heard that peculiar gurgle which told of an emptying of the sac. Under local anesthesia the patient could be instructed to cough or strain and the sac would again fill; this fact made a great difference in the ease of operation. Again under local anesthesia, if an appendix was encountered that should be dealt with, the patient's consent could be had at once. Again the avoidance of nausea and vomiting after the operation was a point of great value in favor of the local form of anesthesia. Among the objections he spoke of the danger, in certain instances, of nervous collapse in hysterical or neurotic patients; this was a point that unquestionably came up. The mind should be engaged and less danger would be run. When called upon to operate in strangulated hernia he said it was the rule rather than the exception that the question was not between the physician and the surgeon, but between the surgeon and the undertaker. In these cases he believed cocaine was to be preferred. The solution used should be carefully prepared. He had been informed that heating cocaine to 212° F. decomposed it into ecboline and several subsidiary alkaloids of little anesthetic power. Dr. Dawbarn therefore had the cocaine baked first and then dissolved in physiological saline solution.

Dr. WILLIAM B. COLEY said he had had no practical experience with local anesthesia in hernia work. In his experience with general anesthesia he had seen but one death, and this occurred in a child from pneumonia. This child had had an attack of measles not long before operation that made her lungs easily affected. Dr. Coley took exception to the remark that it was sometimes necessary to

have the patient cough or strain in order to aid in discovering the sac; it could be found readily enough without such efforts. The sutures might be torn out after general anesthesia, but he said they would not if properly applied. He believed the mortality in the radical cure of hernia was due entirely to other causes than the ether; it might be due to sepsis, etc. Patients did not like the idea of being cut, and he thought the majority of them would prefer general anesthesia on this account. If patients were afflicted with cardiac or pulmonary disease he did not believe they were good subjects for any operation, and they would do better by wearing trusses.

Dr. George E. Brewer said that his experience with local anesthesia in the radical cure of inguinal hernia was very limited, and was due to rather an unusual train of circumstances. The first operation he performed by this local anesthesia method was on a woman with a strangulated hernia, where it was impossible to give general anesthesia. The cocaine was given in the old way, a four per cent. solution being used, and the operation was carried on without pain and with great satisfaction at the time; but the wound suppurated because the cocaine solution was an old one. After seeing Dr. Cushing's article and being much impressed with his results, he made another attempt and found the anesthesia was imperfect. He then visited Dr. Cushing, but unfortunately the local anesthesia had to be abandoned in the operation he saw Dr. Cushing perform, and general anesthesia given. Therefore, he did not deem it wise to pursue the method further. Dr. Brewer acknowledged that in all probability his method was faulty, and he felt satisfied that most of the objections given to the method were purely theoretical. If Dr. Bodine's technique was adhered to he believed that these patients could be operated upon without pain. The ether mortality rate he said was one in from 20,000 to 24,000 cases, but this meant the deaths that occurred on the table; many died from remote effects, and he believed the rate was much higher than most people believed.

The Administrative Control of Tuberculosis.—Dr. Hermann M. Biggs read this paper. He said that remarkably few cities had attempted to adopt efficient measures against this dread disease in this country or abroad. He spoke of the special committee that was appointed several years ago by the New York Academy of Medicine to consider resolutions regarding this work, and this committee reported that such work was inexpedient and unadvisable. It always seemed as though there was opposition somewhere, expressed by the authorities and which was due to the influence of precedence. Now it was universally believed that some kind of supervision of tuberculosis was not only justifiable but necessary. Dr. Biggs then outlined the plan that had suggested itself to him and which he had carried out by the health department. It was adopted nearly twelve years ago, but had been amplified and perfected in minor ways since as the facilities of the department permitted. The administrative control of tuberculosis was considered under the following headings: (1) Compulsory notification and registration of all cases. In 1893 the public institutions were required to report such cases, but the physicians were only requested to do so. This lasted for three and a half years, and then it was required that all be reported and registered. Such notification did not require action on the part of the authorities unless such action was deemed to be advisable. If the patient lived in a poorly furnished room, or in a tenement house, the removal of that patient might be considered necessary and then the authorities would take action. That was the attitude adopted by the sanitary authorities of New York City. If the consumptive was under the care of a physician no further cognizance of the case would be taken after registration. The mere fact of notification and registration acted powerfully in the way of education. During 1903 more than 16,000 cases were reported and during 1904 more than 19,000. (2) Facilities for early and definite diagnosis of tuberculosis. As a rule the authorities offered every facility for free examinations of sputa. Where the physical signs failed to reveal the condition this afforded a ready means of making a positive diagnosis early. Yet he believed it was erroneous to say that one was not dealing with a case of tuberculosis because no tubercle bacilli were present. He emphasized the importance of the earliest possible diagnosis. Many physicians had not the facilities and many were not competent to make these examinations, and it was of great aid to have the city furnish these facilities. In 1904 more than 17,000 examinations were made in the laboratory and the material came almost entirely from private physicians. (3) Education. He said it was difficult to overestimate the importance of educating all the people regarding tuberculosis. Circulars had been printed which were designed to reach the different classes of people, and the public press was also utilized in the diffusion of knowledge. The nature of tuberculosis and the means of prevention were especially dwelt upon. (4) The visitation of consumptives in their homes. In this way verbal instructions could be given, and printed circulars left for the information of the consumptive's family. Then too data could be gained which was of value to the Department. Sometimes it would be demonstrated that the consumptive should be sent to some sanatorium, asylum, etc., out of the city. (5) Disinfection or renovation of rooms vacated by consumptives or after death of the consumptive. In those cases where the premises were very dirty and surroundings bad, renovation must be made by the owner and at his cost. Where materials could not be disinfected thoroughly with formaldehyde they should be removed by the authorities and disinfected with steam without cost to the owner. It was not their wish to entail any additional hardship upon the patient. (6) Provisions made for making repeated visits upon patients in tenement houses when it was impossible or undesirable to move these patients to institutions. (7) Suitable food, especially milk and eggs, should be provided by the authorities in those instances in which the families were destitute and could not obtain them, and when the patients could not be removed to institutions. (8) The sanitary authorities should provide three classes of institutions for consumptives as follows: (a) Free dispensaries; here the cases should be constantly under observation by the district physician and nurse, and if necessary the medicine and food should be furnished free. From the dispensaries suitable cases should be referred to the hospitals or sanatoria. (b) Hospitals for the care of advanced cases. It was necessary and desirable that all such hospitals should be under the care and control of the sanitary authorities, or that they should exercise a general supervision of them. In such institutions patients should be received who violated the rules, or those who were homeless, friendless, and destitute, those that were a menace to the community. Such cases must be provided for by the sanitary authorities at any cost. Also there should be sent there cases living in lodging houses, or in public institutions where there were no facilities for their care. They should be removed by force if necessary. In large cities many cases should be removed from their homes because of the danger to others in the family from the overcrowding. Again there were cases already under the care of other institutions that become dissatisfied and determine to return to their homes; these cases should be taken by the health authorities and retained. Rarely did the Board of Health of New York City have any difficulty in the management of such cases. (c) Sanatoria in the country districts for the care of these patients. When these patients were discharged he said they became great educational factors. (9) The sanitary authorities should see to the regulation as to the care of consumptives. The regulations should apply not only to the general hospitals, but also to the hospitals for the insane and penal institutions. (10) There should be enacted and enforced measures to prevent spitting in public places. The careful disposal of the sputa was very important, and Dr. Biggs thought this to be the keynote in the prevention of the diseases of the respiratory tract. There would be no pneumonia or tuberculosis

except from organisms contained in the secretions from the respiratory tract. These diseases attacked all classes of people and of fundamental importance in the prevention of them was the proper disposal of the sputa. When the mass of people were educated to this view it would be an important factor in the solution of the question of prevention of tuberculosis and diseases of the respiratory tract. A semiannual census of consumptives should be taken in institutions. Sanitary cuspidors should be provided by the health department. Circulars of information should be distributed ; these should be in various languages. The inspectors of tenement houses should report all cases they found. Dr. Biggs closed his paper by asking if the scheme of sanitary surveillance was a feasible and practical one; he believed it was. This had been demonstrated by the experiences in the second largest city in the world, New York City. Were there any serious objections to the enforcement of such a scheme? He answered this decidedly in the negative; none had ever been encountered in carrying on this work. What might reasonably be expected by the enforcement of such measures? There had been a rapid fall in the death rate in New York City, more rapid than in any city in this country, notwithstanding the fact that conditions here were more unfavorable because of the dense population and foreign born population. In New York City there were from 600 to 1,000 people to the acre; abroad there were only 400 or less persons to the acre. During the last ten years there had been a decrease of 40 per cent. in the death rate in children under 15 years of age from pulmonary tuberculosis and tubercular meningitis. Between 1887 and 1903 there had been a decrease of nearly 40 per cent. in the death rate from tuberculosis. The decrease was a real and not an apparent one. This rapid decrease in the death rate was the direct result of the application of the measures referred to in his paper, and Dr. Biggs believed that within the next fifteen years this reduction would be equalled. One could not escape from the conclusion that tuberculosis was a preventable disease, and one of the most preventable. The time was not far distant when the municipality would be considered criminally negligent in its administration of sanitary affairs if such measures as advocated were not enforced.

Dr. John Winters Brannan wished to commend the work Dr. Biggs had done on the tuberculosis problem, and referred to the time, a few years ago, when a number of physicians gathered to protest against the measures proposed at that time and which were just described after having been in effect five or six years. At that time the feeling in Philadelphia was the same as in New York. Under the influence of the work done in New York, Philadelphia and Boston were trying the same measures, and the medical men now were asking that such rules be enforced. Those physicians who, a few years ago, opposed the measures proposed by Dr. Biggs were now his most hearty and enthusiastic supporters.

Dr. Egbert Le Fevre said that years ago there were misunderstandings on both sides. The Board of Health was zealous for control and, from a sanitary point of view, that was correct. People at that time did not understand the differences between communicability, infection, and contagion, and consequently these names were surrounded with undue terror. At that time the discussion was an educational one. But gradually the profession and the laity had been educated, and now they all had a true conception of the disease. The bread winners made up a large proportion of the cases of tuberculosis and he wished to emphasize the importance of opening up public dispensaries for their care and so they could gain advise. He believed the time would come when certain organizations, especially those interested in insurance work, would do as was done in Germany, and have protective unions take up the care and treatment of cases of tuberculosis from purely an economical standpoint; it certainly would be cheaper to have these sanatoria scattered throughout the country.

Dr. Thomas Darlington wished to give credit to Dr. Biggs for the control of tuberculosis in New York City. He referred to a recent article in a medical paper in which the writer assumed that it was a trivial thing to spit upon the sidewalks. He considered the article very vulnerable, and the arguments presented in it would scarcely hold. Dr. Darlington said that it was rare for women to expectorate, and he asked if it was more necessary for men. Spitting was a filthy and disgusting habit, and he said it was a stigma upon the American people. He did not believe that it ought to be necessary to have so many printed signs against spitting as now were seen in ferry houses, subway, surface, and elevated cars, etc. To-day it was without any doubt necessary to have them, but he hoped that they soon would be abandoned. He regretted very much that any medical journal should have permitted the publication of such an article as the one he had referred to; it might be all right in the daily newspapers, but not in a reputable medical journal. He did not believe that receptacles should be placed all over the city of New York for people to spit in; that portion of the law should be wiped out. Let people carry their own receptacles. If people were not consumptives he did not believe there was much harm from swallowing the sputa. He said that there would be printed 1,700,000 circulars which were to be placed in the school books of children which no doubt would serve as an educational factor for coming generations.

Drs. Cubin, Cooper, and Bryan also discussed the paper.

NEW YORK ACADEMY OF MEDICINE.

Section on Medicine.

Stated Meeting, Held March 21, 1905.

Dr. Charles H. Lewis in the Chair.

The Present Clinical and Bacteriological Status of Vincent's Angina.—Dr. William N. Berkeley read this paper. He said that this disease from a clinical point of view might be defined as a localized, acute, or subacute inflammation, usually ulcerative, less often membranous, of the mouth and fauces, in which below the diseased tissue certain bacilli and spirocheta were found in virtually pure culture. The etiologic nexus between the ulcer and the germs was not yet scientifically established, but those who had studied the germs and ulcers together had become convinced that the relation between the two was casual. He reviewed the history of the affection from the early eighties, when the bacilli and spirilla were apparently known to Miller. The synonyms for this disease were numerous. It was known as plant angina, ulceromembranous angina, ulceromembranous stomatitis, angina diphtheroides, "bazillen-spirillus angina," and others. In 1898 Vincent's accounts of the affection gained the attention of the medical world, and his name had now been accepted as a convenient designation of the condition. He said the literature of Vincent's angina was now enormous. The disease might be called relatively rare both in Europe and America, however the disease had been repeatedly noted in all of the large clinics in New York during the past four years. Sobel and Herman had given an excellent account of 12 cases seen in the summer and autumn of 1901 at the Good Samaritan Dispensary, and he mentioned numerous other cases which had been reported. He had notes of 27 cases seen at his own clinic in the last three or four years. Since Vincent's earliest papers many series of cases have been reported from abroad, and there are now many hundreds of cases on record—sufficient to warrant some reliable clinical data. The lesion was usually a circumscribed penetrating ulcer. It might spread laterally as a false membrane, or the two processes might be combined. The first was the usual condition. The site of the lesion in the majority of cases was the tonsil, usually one, rarely both. Out of 22 cases of Dr. Berkeley's series the right tonsil was involved 14 times. A case of average severity was apt to begin at the upper angle of the tonsil as a grayish necrosis quite similar to diphtheretic membrane and from ⅛ to ¾ of an inch in

diameter. When this necrotic covering was broken a penetrating ulcer was disclosed from ½ to ¾ of an inch in depth. The margins were steep and irregular, and the bed was covered with pus and saliva. It bled easily from contact with food or the swab. Sometimes the whole of a hypertrophic tonsil was involved in a destructive process which leveled off the organ as though it had been removed by operation. Smears from beneath the slough showed pus cells, necrotic fragments, mucus, and a pure or nearly pure growth of the bacteria. The reaction of the exudate was usually slightly acid to litmus. The tonsil and fauces were usually red and odematous, the neck on the affected side slightly swollen, and one or two large lymph nodes were generally present. The lips, gums, cheek or tongue, or all combined might show a pseudomembrane or one or more ulcers in which the bacteria were present in large numbers.

Bacteria of the same appearance quite regularly occurred also in the pus of pyorrhœa alveolaris, though the causal relation was here much more doubtful. The majority of cases occurred in children. In Dr. Berkeley's series of 29 cases 13 were between the ages of 3 and 6 years; 9 between 6 and 10, 3 between 10 and 20, 4 between 20 and 33 years. Fourteen were male, 15 female. There was probably no special seasonal prevalence. The introductory symptoms were usually those of subacute sore throat—without a distinct chill, but with headache, malaise and a temperature of from 99 to 102.5 degrees. In ordinary cases the general symptoms subsided in from three to four days. Locally there was moderate pain and dysphagia. There might be slight salivation. The results of examination of the urine and differential counts of the leucocytes were negative. The superficial similarity of Vincent's angina and tonsillar diphtheria in the earlier stages was very great. As to the communicability of the disease, so far as the present weight of experience went it might be broadly stated that it was communicable. There was abundant evidence that Vincent's angina might complicate or be complicated by various other zymotic diseases of the mouth and pharynx—notably diphtheria, syphilis, scarlatina, scurvy, and the ordinary coccus-anginas. The baccili and spirilla are also apt to appear in pure growth on tonsil-stumps after amputation and in varying quantities in aphthous ulcer of the buccal mucosa. The most important complication was diphtheria. As systematic complications, polymorphous erythemata, temporary albuminuria, suppurating axillary nodes, and painful and swollen joints had been reported, but were probably coincident streptococcus infections. The cases ordinarily healed in from one to three weeks, lasting longer in patients with unhealthy mouths. The prognosis as to life was probably always good. Neither predisposition nor immunity appeared to follow in a single attack. The clinical aspect of the disease was so characteristic that it could usually be recognized without the microscope, though microscopic examination was essential to avoid error. A sterile swab was first plunged into the depth of the slough, a smear made at once, fixed, and while still warm, flooded with carbolic fuchsin. Ten seconds' contact was enough. The slide was then washed, dried, and examined. To be perfectly sure it was wise to examine both a fresh mucus from the swab and a culture. In treating his own cases Dr. Berkeley put the patient to bed during the existence of the fever, and provided a gargle of sodium bicarbonate and boric acid, equal parts, in a sufficient quantity of hot water. If complications arose they should be treated rationally. Vincent recommended tincture of iodine swabbed into the ulcer vigorously every day. Methylene blue had also been used. Many other remedies had been suggested, but in the experience of the speaker they were needless. Isolation should be practiced to a reasonable degree.

The germs commonly called Vincent's bacteria were morphologically two in number. (1) A spindle-shaped bacillus named by Vincent bacillus fusiformis; this name was only provisional. The bacillus was 7-14 in length, ½ in thickness and stained fairly with most anilin dyes, very brightly with carbol-fuchsin (Ziche's solution). It was usually straight, but might be curved or even "S" shaped. The germ was easily identified. If it showed certain peculiarities of shape in the first examination it would preserve these marks throughout the case. (2) A spirillum, more properly a true spirochete, one-half or one-third as thick as the bacillus, staining much more lightly as a rule, and showing from 2 to 5 spiral turns, which might be tight or loose. On the cover glass the spirillum had usually a rectilinear axis, but might be doubled or twisted on itself. Its axial length was 15 to 25 microns. It was generally agreed to be motile, but stained flagella had not been mentioned so far in literature. It was also beaded at times, but less often than the bacillus. Both these germs had probably been known for a long time as saprophytes in many apparently normal mouths. The occurrence of the germs in decayed teeth, inflamed gums and aphthous ulcers had also been noticed by many. The speaker said that it was rather surprising that in spite of an immense amount of ingenious research these germs still refused to grow in pure culture. In some instances the organisms had been successfully carried in a mixed growth, through a few transplantations, but they were rapidly overgrown by contaminating germs and soon disappeared. Inoculation of the ordinary mixed cultures into animals had been followed by lesions in which the germ, still mixed, could be recovered. Dr. Berkeley said that he had been experimenting for over two years without success. The peculiar association of two such dissimilar germs as a pathogenic entity had excited much discussion. The French writers had accepted the condition as a peculiar "symbiosis," while others had suggested that the two were morphological variants of a single germ.

Dr. Emil Mayer opened the discussion by referring to the first case reported by him. The patient was a man, 28 years of age, who had a peculiar ulceration on the tonsil, which would surely have been taken for a specific ulceration at first glance, having many of the signs of syphilitic lesions. Dr. Libman declared it to be of an entirely different nature. Because of the possibility of the practitioner making some error the patient was asked to go to the laboratory, which he did. A correct diagnosis was then made, and this was the first case reported by Dr. Mayer. From 1893 to 1901 about sixty papers on this subject were presented abroad, but not one in this country. A point of special interest was the differential diagnosis. He wished to combat the statement that the majority of these cases were seen in children; the majority occurred in adults. The diagnosis lay between Vincent's angina, diphtheria, and syphilis. If specific disease a course of the mercurial treatment would cause the ulceration to promptly heal. If diphtheria the culture method would soon make the diagnosis. Dr. Mayer's treatment consisted in the application of Lugol's solution, directly with a swab or by means of a spray. Nothing should be so violently applied as to bruise the parts. A spray of permanganate of potassium was also of value.

Dr. William K. Simpson thought that undoubtedly our present knowledge of Vincent's angina cleared up the diagnosis of a certain class of cases seen formerly when physicians were at a loss to know just what they were. Some of these cases had been passed on as cases of specific disease, and some had been given the credit of having been cured by specific treatment. The cases occurred in young adults and gave all the appearances of an ulceration which they knew nothing about. The lesions cleared up without treatment. With regard to the location, especially of the most common variety, the tonsillar, it was found that the ulceration appeared more often in the upper portion of the tonsil and passed under the superior border of the anterior pillar. He believed the disease was much more frequent than generally supposed. This disease was an entity. It was first thought to have been a remnant of some type of ulceration. The microscope gave a positive means of diagnosis, although in the early stages it could easily be confounded with diphtheria or follicular tonsillitis. In the

early stage he did not think it would be confounded with specific ulcerations. As an axiom in lesions of the throat he said that if lesions persisted over two weeks one could be fairly positive of some constitutional disease existing. After two weeks one must differentiate from the tertiary ulcerations.

Dr. E. LIBMAN took up a consideration of the organisms found in these cases. There were found fusiform bacilli which were anaërobic and which were also found in other necrotic affections. There were other organisms found which looked like these fusiform bacilli which were also anerobic. The fusiform bacilli that were found in Vincent's angina could not at present be successfully cultivated artificially. Welsh of Baltimore some time ago had stated that the spirocheta of relapsing fever was a division form in the life history of trypanosomes, and it was probable that these spirochetæ were of the same nature. Wright of London had shown that the fusiform bacillus and the spirocheta found in Vincent's angina were one and the same organism because found in transition forms. If this was so it was evident why attempts at cultivation had been unsuccessful, because trypanosomes could not be cultivated except on blood media.

Dr. SOBEL said that the organisms had been frequently found by him in children under 10 years of age. During the past four years he had seen 29 cases; all were limited to the tonsil except four, which had associated lesions in other portions of the mouth. When so associated the difficulty of diagnosis was increased. He believed the disease to be far more frequent than generally supposed, and it was common in all the walks of life. In a paper published some years ago he reported 12 cases and divided them into the clinical, microscopical, and bacteriological. Clinically the cases differed somewhat from those reported by Dr. Berkeley. The constitutional symptoms were practically nil, the temperature ranging from 99.5° to 100° or 101°. There was no headache or constitutional symptoms. The children complained of pain in the throat on deglutition and there was a submaxilar adenitis. A striking feature was the lack of proportion between the constitutional symptoms and the objective symptoms. There was no fetor to the breath. The resemblance to diphtheria during the first twenty-four hours was quite marked, but after that time the diagnosis was easily made. The diagnosis was made not from the culture, but from a smear, and the technique was exceedingly simple. The doctor here described his method of making a smear, and emphasized the importance of not simply applying the swab directly to the mass, but of pressing it firmly against and into the necrotic mass. If the necrotic structure be entered with the swab one would probably obtain a very clear-cut picture. In making a differential diagnosis it should be borne in mind that in Vincent's angina there was an ulcer from the beginning, which spread deeply as a rule. The vacuolations seen he believed were due either to a contraction of the protoplasm or to a regenerative form of spirillum. The prognosis was good if no complications arose. He had one case that lasted 42 days in spite of treatment. A remedy that was efficient in one case might not be in another. He placed more faith on Lugol's solution, though sometimes he used chromic acid.

Dr. J. FINLEY BELL reported a case of Vincent's angina that he had seen at the Englewood Hospital.

Dr. HERMAN said that it was not a bacillus, but a segment of a spiral, or vibrio. There was a flagellum attached to the capsule which surrounded the body of the organism. In every case fusiform bacilli were found. Attempts to grow it on blood agar had been unsuccessful. It seemed as if the lesion spread as in diphtheria but, as a matter of fact, it spread simply by contact; sometimes two lesions occurred with a bridge of tissue between the uvula and tonsil. The odor was due to the spirocheta. The lesion he believed to be more common in children. The removal of the entire tonsil might be justifiable in certain cases.

A Case of Acute Polyarticular Gout.—Dr. N. B. POTTER reported two cases. The first was a man who was taken ill December 24, and admitted to the hospital the day following with what appeared to be an acute articular rheumatism. He was placed on large doses of salicin, 400 to 450 grains being given in twenty-four hours, but without any abatement of the symptoms. It was a polyarticular affection. He changed the therapy and placed the patient on colchicin, 1-100th of a grain every two hours, and shortly after the symptoms improved, the joint inflammation subsided and the patient became very comfortable. The patient entirely recovered. The second case was taken with articular difficulty. Before this, following exposure, he had had some polyarticular trouble. Under large doses of salicin he failed to improve. There was redness, swelling, and pain, with fever, but no improvement followed these large doses. He changed the therapy and placed him on colchicin with a subsidence of all symptoms.

Dr. CHARLES C. RANSOM, who saw the cases at the City Hospital, said that he had been taught that such involvement of the joints in the way described were due to rheumatism and, therefore, the report of these cases was especially interesting. As a matter of fact such clinical pictures were impossible to diagnose from the joint involvement alone. He saw a case at the hospital which began as an acute inflammation of the big toes of both feet. The man had some temperature and entered the hospital chiefly because he was unable to work. The diagnosis of gout was made, and colchicin was given for two weeks without any abatement of the symptoms. It was learned that some six or seven weeks prior to entrance to the hospital he had had an attack of gonorrhea. He was taken off colchicin and the urethra treated, which was followed by a disappearance of all symptoms. In this case there was the classical development of gout, and yet the treatment proved that it was not gout at all. In many instances, he said, the joint lesions could be diagnosed by the treatment employed.

A Sterile Purulent Joint, Following Acute Articular Rheumatism.—Dr. H. S. CARTER reported the case of a youth, 19 years old, with no history of any specific disease, whose illness began in June of last year with pains in the legs, but without any local signs. Four days later he had a typical attack of acute articular rheumatism. Alkalies and salicylic acid were given, but this caused carbolic acid absorption which appeared in the urine and had to be stopped. The temperature and pulse were moderately elevated. Fluid collected in the knee joint of the left side. The pain was considerable in spite of local applications. The joint was considerably swollen; the skin over the joint became reddened, later pale and resembled somewhat a tubercular joint. From June 1 until July 5 the condition persisted and with but little change. There was no sweating or any wide range of temperature. Thirty-five days after the onset of the trouble the joint was aspirated and no irrigation was used. The morphological examination followed; there were two layers above the fluid resembling synovial fluid, while below there appeared pus, which contained 99 per cent. polymorphonuclears. No tubercle bacilli were found. No guinea pig inoculations were made. The local symptoms subsided and convalescence was rapid and uninterrupted.

Dr. HENRY W. FRAUENTHAL said that the source of infection in these cases might be from the urethra, and many men had cited cases in which the gonococccus was found in the joint during the first three or four days, but was not found ten or fifteen days after. He had himself reported some twelve cases with the same findings.

Recent Studies in the Diagnosis of Rabies.—Dr. DANIEL W. POOR, of Orange, N. J., read this paper. (See page 568.)

Dr. HARLOW BROOKS did not believe the rabic tubercle was at all characteristic in this disease, and said that the changes in the ganglionic cells were not to be relied upon; they were closely simulated by post-mortem changes. With regard to the changes in the posterior ganglionic cells, he stated emphatically that he had no use for them for diagnosis because the same changes were to be noted in tabes dorsalis, chronic alcoholism and syphilis.

Dr. Robert J. Wilson said that any one who had seen people who had been bitten by rabid animals knew just what their anxiety was, and how desirous they were not to take the treatment. He referred to some cases he was called to see three months ago; he was asked to delay treatment until it was positively known whether or not the dog was rabid. A smear was taken, and the Negri bodies or corpuscles were found in a few hours. Before three o'clock that same afternoon the treatment was instituted.

Dr. Charles H. Lewis said that a short time ago he was called to see a woman who had been bitten by a dog. There was no reason for suspecting the dog to be rabid. He saw her one and a half hours after she was bitten, and he cauterized the wound thoroughly. The dog was then taken to a veterinary surgeon, who thought the dog had rabies. At five o'clock that afternoon the diagnosis of rabies was made, and the woman received her first injection of antirabic serum. Her last injection would be given the following day (Wednesday). The dog died on the day after he had bitten the woman, and the disease apparently was in a very virulent form. Dr. Poor took charge of the dog's brain and made the examination, but had not as yet reported his findings.

Dr. Poor, referring to the case cited by Dr. Lewis, said that the diagnosis was easily made from the brain findings, although it was taken from the animal on the second day of the disease. As a rule, when animals showed early symptoms of rabies they were at once killed and then the findings were not so marked. Twenty-one full days' treatment was employed. By means of smears the diagnosis could be made in a few hours. Of course, a negative diagnosis from smears was often of less value than a diagnosis made from cultures, chiefly because there was much less tissue in the smears. The tissue in smear work, too, must be in a fresh state.

Election of Officers.—*Chairman,* Dr. Charles H. Lewis; *Secretary,* Dr. E. E. Smith.

Philadelphia County Medical Society.

At a stated meeting, held March 8, Dr. Charles W. Burr exhibited "A Case of Fracture of the Fifth Cervical Vertebra, with Partial Recovery." The patient was a man 56 years old, who, in November, 1898, fell from a wagon, striking the neck and shoulders. There was at first great pain in the back of the neck, shoulders, and arms, with loss of power in the upper extremities. Six weeks later the man was able to walk, though with some rigidity in the legs. The arms were held close to the side of the body. With effort the forearms could be flexed on the arms and the arms could be slightly abducted. The grasp was enfeebled. Sensibility was everywhere preserved, and there was no muscular wasting. The biceps and triceps jerks were absent, and the knee jerks were increased. There was pain in the back of the neck and in the arms, and sensitiveness to pressure along the spine. The muscles of the neck were stiff, and the head was bent forward on the chest. The movements of the head were restricted and attended with pain. There was slight spasmodic retention of urine. The bowels acted normally. From all of these symptoms there was great improvement. A skiagraph disclosed a fracture of the laminæ and spine of the fifth cervical vertebra, with dislocation and possibly fracture of the body of the bone. Dr. J. Madison Taylor read a paper entitled "How Can the Physician Profit by Preventive Medicine." He contended that the mere alleviation of human suffering is only a part of the prerogatives of the educated medical expert. The effects of preventable disease must be regarded as so much loss of wage-earning dynamics. In order to attain the best results the physician must become an expert in the conservation and development of the bodily energies, through the principles of hygiene in all its broad compass. He must be prompt to recognize the prephenomena, the omens of disease. He must become a practical psychologist and give adequate attention to psychic progress and variants, ethical peculiarities and limitations. He must become the guide, philosopher, and friend of those with whom he is associated. Dr. W. Wayne Babcock read a paper entitled "The Osmic Acid Treatment of Tic Douloureux." He reported the case of a man 55 years old, who for more than thirty years had suffered from infraorbital neuralgia, first upon one side, and later upon the other side, and for relief from which he had submitted to several surgical operations. Finally the inferior dental nerve was exposed from within the mouth, and twelve minims of a freshly prepared two per cent. solution of osmic acid were injected into the trunk of the nerve. At a later date other affected nerves were treated in a similar manner, with marked relief in each instance. Dr. W. G. B. Harland read a paper entitled "The Problem of the Treatment of Tuberculosis of the Larynx." He defined the disorder as an insidious, intractable subepithelial infection, the germs of which are hidden in and beyond the limits of the apparent disease. The local lesion ordinarily represents an extension of the morbid process from elsewhere, and affords evidence of impairment of the powers of resistance. Many of the forms remain harmless indefinitely if local irritation is prevented and the general health is improved. Although ulceration, when it occurs, has little tendency to heal, it often does so under treatment. This should be directed to liquefying and removing secretions from the upper air tract, relieving congestion, allaying irritation, destroying tubercle bacilli, and removing the tissues destroyed at a result of their activity.

Philadelphia Pediatric Society.

At a stated meeting, held March 14, Dr. Eleanor C. Jones exhibited four members of a family of five children with "Multiple Exostoses." A similar condition existed in the father, who was a confirmed alcoholic, and whose mother likewise had been an alcoholic. Dr. D. J. Milton Miller exhibited "A Case of Fetal Chondrodystrophy." The patient was a boy 7 years old, with the characteristic depression of the bridge of the nose and a large head. The long bones generally were shortened from defective development of the epiphyseal cartilage. The stature was abbreviated by reason of the shortening of the bones of the lower extremities, while the trunk corresponded in size with that of a normal child. Dr. Charles W. Burr exhibited "A Case of Stuporous Insanity at Puberty." The patient was a boy 13 years old, who had been a heavy smoker of cigarettes, and had, besides, a most unfavorable environment. From having been an ordinarily bright lad, he developed delusions of persecution, and subsequently became taciturn and uncommunicative, and eventually apathetic and apparently oblivious to his surroundings. He failed to control his sphinsters, and took food only when it was forced on him. For a time the members exhibited waxy rigidity. He became greatly wasted. The first sign of a change for the better was sudden laughter at what appeared to him as a ludicrous incident. After this, coincidently with improvement in the general nutrition, indications of improvement in the mental state made their appearance. The prognosis was considered fairly good. Dr. J. B. Crozer Griffith reported "A Fatal Case of Chorea." The patient was a child, in whom the movements were characterized by their great violence. Symptoms of acute endocarditis were present. Death resulted apparently from exhaustion, in spite of most active treatment. Autopsy disclosed the lesions of malignant endocarditis, but examination of the nervous system was not permitted. Dr. R. Max Goepp reported "A Case of Necrotic Stomatitis following Pneumonia and Measles." The patient was a child, in whom inflammation of the tissues of the cheek developed, with necrosis, but not progressing to gangrene. Diphtheria bacilli were found in cultures, but under treatment recovery ensued. The case must be considered as belonging in a category intermediate between ulcerous and gangrenous stomatitis. Dr. Goepp reported also "A Case of Malignant Scarlet Fever." The patient was a child, pre-

senting sore throat, cultures from which failed to disclose the presence of diphtheria bacilli. In view of the existence of scarlet fever of mild grade in another child in the family, a diagnosis of this disease was made, although no exanthem appeared. Death took place at the end of forty-eight hours.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

WHARTON AND STILLE'S MEDICAL JURISPRUDENCE. By ROBERT AMORY, A.M., M.D., and ROBERT L. EMERSON, A.B., M.D. Vol. II. POISONS. Fifth Edition. 8vo, 858 pages, leather. The Lawyers' Co-Operative Publishing Co., Rochester, N. Y.

A TEXT-BOOK OF THE PRACTICE OF MEDICINE. By HOBART AMORY HARE, M.D., B.Sc. 8vo, 1119 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia. Price, $5.00 net.

MEALS MEDICINAL: WITH "HERBAL SIMPLES," (OF EDIBLE PARTS)—CURATIVE FOODS FROM THE COOK; IN PLACE OF DRUGS FROM THE CHEMIST. By W. T. FERNIE, M.D. 8vo, 781 pages, leather. John Wright & Co., Bristol, England. Price, 7/6 net.

CONSERVATIVE GYNECOLOGY AND ELECTRO-THERAPEUTICS. A PRACTICAL TREATISE ON THE DISEASES OF WOMEN AND THEIR TREATMENT BY ELECTRICITY. By G. BETTON MASSEY, M.D. Fourth Edition. 8vo, 467 pages, illustrated, muslin. F. A. Davis Company, Philadelphia. Price, $4.00 net.

MONOGRAPH SUPPLEMENTS. THE PSYCHOLOGICAL REVIEW. Edited by J. MARK BALDWIN, HOWARD C. WARREN and CHARLES H. JUDD. Yale Psychological Studies. Vol. I. No. 1. 8vo, 226 pages, illustrated. The Macmillan Company, New York.

AILMENTS OF WOMEN AND GIRLS. By FLORENCE STACPOOLE. 12mo, 238 pages. J. Wright & Co., Bristol, England. Price, 2/- net.

THE INTERNATIONAL MEDICAL MANUAL: A YEAR BOOK OF TREATMENT AND PRACTITIONER'S INDEX. 1905. By various authors. 8vo, 644 pages, illustrated, muslin. E. B. Treat & Co., New York. Price, $3.00.

VERÖFFENTLICHUNGEN AUS DEM GEBIETE DES MILITÄR-SANITÄTSWESENS. Heft 28. BEITRAGE ZUR SCHUTZIMPFUNG GEGEN TYPHUS. 8vo, 63 pages, paper. August Hirschwald, Berlin.

Dr. JESSNER'S DERMATOLOGISCHE VORTRAGE FÜR PRAKTIKER. Heft 14. DIAGNOSE UND THERAPIE DES EKZEMS. I. Tiel: DIAGNOSE. Von Dr. S. JESSNER. 8vo, 50 pages. A. Stuber, Wurzburg, Germany. Price, M. 0.80.

DISEASES OF THE SKIN, THEIR DESCRIPTION, PATHOLOGY, DIAGNOSIS, AND TREATMENT WITH SPECIAL REFERENCE TO THE SKIN ERUPTIONS OF CHILDREN AND AN ANALYSIS OF FIFTEEEN THOUSAND CASES OF SKIN DISEASE. By H. RADCLIFFE-CROCKER, M.D., F.R.C.P. Volumes I. and II. Third Edition. 8vo, pp. 1-727 and 728-1466, illustrated, muslin. P. Blakiston's Sons & Co., Philadelphia.

DISEASES OF THE HEART. By EDMUND HENRY COLBECK, B.A., M.D., B.C., F.R.C.P., D.P.H. Second Edition. 8vo, 350 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, $2.50.

ERRORS OF REFRACTION AND THEIR TREATMENT. By CHARLES BLAIR, M.D. 16mo, 103 pages, illustrated, muslin. John Wright & Co., Bristol, England. Price, 2s. 6d. net.

MEDICAL PHILOLOGY. By L. M. GRIFFITHS, M.R.C.S. Part I. 16mo, 100 pages, card-board. J. W. Arrowsmith, Bristol, England.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 8, 1905:

	Cases.	Deaths.
Measles	422	13
Diphtheria and Croup	339	27
Scarlet Fever	259	7
Smallpox	4	.....
Chickenpox	94	
Tuberculosis	441	201
Typhoid Fever	26	13
Cerebrospinal Meningitis	191	110
Typhus Fever		
Yel ow Fever		
Cholera		
Totals	1,776	371

A New Theory of Fever.—T. G. Atkinson, in explaining this theory, states that in the production of carbon dioxide heat is liberated; in the formation of water, as accomplished by nature in the human body, heat is absorbed. The quantity of water formed bears a definite and constant relation to the amount of carbon dioxide produced, and therefore to the extent of oxidation performed. The greater the oxidation, the larger the amount of carbon dioxide produced and heat liberated; the larger the amount of carbon dioxide produced and heat liberated, the greater the quantity of water formed and heat absorbed. The writer offers this as a natural and logical cycle of processes by which the generation and the loss of body heat are automatically and constantly balanced, leaving to the lesser functions of radiation and evaporation the simpler task of draining, not the excess heat, but the constant level of normal heat. After the water is formed it becomes one of the most potent factors in distribution and surface elimination by virtue of its high degree of specific heat. If this theory is allowed, a serious elevation of temperature can result from only one source of disturbance—from any condition interfering with the free formation of water in the body. Water is the sine qua non of fever therapeutics—water in all forms in abundance, and by every available means of administration. While no amount of water ingested can perform the function of water-production and lower the temperature level at the fountain head, yet by virtue of its high specific heat it is the ideal agent for maintaining a steady level of the normal heat-tide. Little can be done with drugs. The writer concludes that if, in the present stage of our knowledge, we possessed the means of checking the fever process, we might ignorantly thwart one of Nature's safeguard processes and let loose upon the patient far graver troubles which we should be powerless to remedy.—*The Medical Standard.*

Leukopenia in Malta Fever.—Axisa from his experience in the hospital for Europeans at Alexandria says that the diagnostic triad of diazo reaction, splenic tumor, and leukopenia, which is so characteristic of the early stages of typhoid fever, is also encountered quite regularly in cases of Malta fever. The only means of early differentiation lies in the serum reactions and these, of course, are sometimes late in appearing. It also happens that the serum of a patient may agglutinate both typhoid bacilli and the coccus of Bruce, as in a case described by the author, so that diagnostic embarrassment may ensue. Of twelve cases of Malta fever, in which the leucocytes were counted ten days to four weeks after the beginning of the disease, values ranging from three to eight thousand to the cubic millimeter obtained, the majority being very low.—*Zentralblat f. innere Medizin.*

Inhalations of 95 Per Cent. Alcohol.—E. B. Silvers calls attention to the inhalation of alcoholic fumes in cases of head colds and grippe attacks. In laryngeal and bronchial

cases he orders the inhalations for ten or more minutes three or four times a day. The first effects are not pleasant, as there is considerable smarting with much defluxion from the eyes. But this soon passes off and is followed by a pleasant clearing of the nasal passages and prompt relief. If it is breathed at the start through the mouth, and exhaled by the nasal passages, it will smart less. When giving it to children it is well to add a perfume, the oil of wintergreen being best, on account of its antiseptic properties. A little salicylic acid extra can be added, especially in diphtheritic cases. The writer takes a section of an unfolded newspaper, approximates the two opposite edges, somewhat overlapping them, and fastens them with a large safety pin. At the apex of the cone he secures an unfolded handkerchief. In using it he has the eyes out, but the nose and mouth covered. The cone can be readily renewed. This method aborts a cold and prevents it from traveling down and affecting the lungs. The hawking and strangling, so often incident to a cold in the head, are easily prevented, and sleep is readily induced if the treatment is used freely before retiring.—*Journal of the Medical Society of New Jersey.*

Treatment of Advanced Cardiac Dilatation.—R. A. Flemming has had very good results in the treatment of cardiac dilatation by massage, passive movements, and modified resisted exercises. He believes the method to be useful as an adjunct to rest and cardiac tonics in many cases of cardiac dilatation, other than cases of acute endocarditis. It is in extreme degrees of dilatation in which its cautious use has yielded striking results. In none of the writer's cases was the entire series of exercises as prescribed by Schott carried out. They were limited to such movements of the arms and legs as could be carried out with the patient in bed, and no particular movements were ordered. Fatigue was never permitted. When the resisted exercises were completed, the patient was allowed to get up and a fw minutes' slow walking replaced the exercises. The period of time given up to this treatment varied with each case. The writer reports ten cases in which he has used this treatment, with eight successes, or moderate successes. He thinks that the systematic trial of this method is warranted by his results. In over half of his successful cases, considerable periods, varying from six months to over two years, have elapsed without any breakdown of compensation. One case has relapsed, although it is not a complete failure.—*The Scottish Medical and Surgical Journal.*

Some Newer Aspects of the Pathology of Fat and Fatty Degeneration.—Henry A. Christian emphasizes the following points: Osmic acid does not stain all forms of fat and fat alone, and so is but an imperfect method of demonstrating fat. Sudan III and Scharlach R, though having disadvantages, give more satisfactory results. Visually demonstrable fat is present normally in very many cells of the body, while extractive fat occurs in practically all of the tissues. Under abnormal conditions visually demonstrable fat appears in cells in increased amount, and is an index of cell injury. Fatty infiltration is the physiological appearance of fat in normal cells, and fatty degeneration is the appearance of fat in injured cells; the fat is an index rather than the direct result of the cell degeneration. In both, the origin of the fat is probably the same and mainly from without the cell by transport from fat depots elsewhere, but may arise within the cell from fat-related bodies, not from proteid.—*Bulletin of The Johns Hopkins Hospital.*

Modern Treatment of Leprosy, Especially with Chaulmoogra Oil.—Alberto Serra gives us the result of his treatment of leprosy with mercurials, cacodilate of soda and chaulmoogra oil. The mercurial treatment ameliorates somewhat the condition of the leper. Sublimate is to be preferred to calomel because it is better borne by the patient and brings better results. Cacodilate of soda is useful in giving some general improvement, increase of body weight, of red blood corpuscles and hemoglobin, and rendering him more resistant to the poison. Chaulmoogra oil is the most useful remedy of all. It may be given by mouth, though it produces gastric disturbances in some persons. It may be also given by injection. It aids in the repair and cicatrization of ulcerations; has the power of modifying the leproma and infiltrations, and aids in absorption of them; it improves the general condition; it has a specific action against the lepra bacillus superior to all other remedies.—*Giornale Internazionale delle Scienze Mediche,*

Experimental Production of Concretions in the Pancreatic Ducts.—Nicola Pende, by tying the duct of the pancreas in rabbits, produced concretions in the duct. He examined the glands and the concretions, and gives us his conclusions thus: Calculi of the pancreas are not necessarily connected with an ascending infective process either in the excretory ducts, or arising from the blood. This may be the case sometimes, but in most cases there is a pancreatic sclerosis, with atrophy and destruction of the secreting cells, produced by substances circulating in the blood, such as alcohol and toxic products of syphilis and rheumatism, producing modifications in the pancreatic juice. The same factors may irritate the mucous membrane of the excretory ducts, and with desquamation of the cells, form an organic nucleus for the concretions, and favor their formation by deposit of calcareous salts. A simple obstacle to the flow of the pancreatic juice, acting on the gland, may produce the same effects.—*Il Policlinico.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended April 8, 1905:

VISUAL FUNCTION THE CAUSE OF SLANTED HANDWRITING; ITS RELATION TO SCHOOL HYGIENE, SCHOOL DESKS, MALPOSTURE, SPINAL CURVATURE, AND MYOPIA.

BY GEORGE M. GOULD, M.D.,
PHILADELPHIA.

Slanted Handwriting is Bad, but not because of Bad Reasons.—Careful and trustworthy statistics show that on the average 27 per cent. of the pupils in the primary grades of the schools of Europe have lateral spinal curvature. The fact is as terrifying as the greatest in pathology, as bad, for instance, as the prevalence of tuberculosis. There is no reason to doubt that American children are less scoliotic than those of Lausanne, Dresden, etc. If not actually crying out against slanted handwriting and school desks as the causes of this appalling disease, almost all orthopedists and school hygienists admit or suggest it. And yet slant handwriting is not only not the cause of the writing malposture and of scoliosis, it is only a minor effect of the writing malposture. It is not only an effect, but, bad as it is, it is a method of avoiding worse malposture. To no one could such a style of writing be more repulsive than to me, and yet, as one must so often emphasize, the bad reason does not make it bad. The reasons for vertical as, slanted handwriting must be scientific and true or the slanting will never be done away with. There are considerations very different, and of infinitely more importance than the slanting itself, why such writing must be abolished.

Factors of the Writing Malposture.—All acts or habits are wrong some of the time, and some acts or habits are partly wrong all of the time. Only the act of writing, as commonly carried out, is wholly wrong all the time.

1. In a state of rest every object illustrates and obeys the law of gravity, equilibrium, or architecture, which demands that its center of gravity must be vertically above its base or point of support. A feeling of strain or irritation arises in the mind when natural objects do not conform to this law. Tumbling-down chirography does not obey this law.

2. The letters of the alphabet are conventionalized pictures or ideograms of the pictograms or pictures of natural objects—the ox, horse, camel, door, window, hook, serpent, hand, fish, water, eye, mouth, head, etc. These prototypes, of course, obeyed the law of gravity in Phoenician and Semitic times as they do now. The modern written letters of the alphabet should do the same.

FIG. 1.—[illegible] of astigmatism in the dominant eye that compelled the head-tilting, depression of the right shoulder, etc., and caused curvature of the spine.

[illegible] curvature of the spine caused by a peculiar axis of astigmatism.

3. All printed and type-written letters, and musical notes preserve the erect position. The handmade letters should conform to the rule.

4. The slant method of writing is a result of the writer's personal difficulties, but the character of the

Fig. 3.—The hand in the writing posture as usually considered, but not practiced, because to the writer the writing-field is hidden by the thumb, finger, and holder. An actual view of the hand with the writer's head displaced.

writing is, or should be, dictated by the consideration of the reader's sake, not because of the writer's personal or pathologic trouble.

5. More important than all the foregoing is the fact that the vast majority of all persons have some astigmatism, and about 95 per cent. of all astigmatisms are at or about the axes 90° and 180°, and such eyes demand the prevailing lines of things seen at 90° or 180°.

Even if no astigmatism is present, or if that which is present is not in the neighborhood of 90° or 180°, the habit of equilibrium, and the inheritance from all ancestors of the habit of holding the head erect and of seeing with the eyes coincident with the usual 90° and 180° axes, would compel the customary position.

The secondary factors, which determine the posture and malposture of the body, and the character of the handwriting, vertical, slanted, or otherwise improper, are:

1. The position or posture of the head.
2. The position or posture of the body.
3. The location of the paper upon the desk.
4. The angling or skewing of the paper as regards the right angles of the desk top or writing board.
5. The flatness or inclination of the desk top or writing board.
6. The relative height and distance apart of the desk and seat.
7. The position of the hand, method of holding the penholder, etc.
8. The necessity of parallelism between the vertical axis of the head, or what is the same thing, of the 90° axes of astigmatism of the eyes, and the vertical lines, real, supposed, or presented by the formed lines of the written letters.
9. The relative position of the right or dominant eye, and the unhindered meeting of the visual axes of both eyes, upon what may be called the writing field, *i.e.* the space at and about the pen-point.

In other articles (*Popular Science Monthly*, August, 1904: *Ophthalmology*, October, 1904) I have explained the terms, *dominant eye*, and *dextrocularity*. The relation of the writing malposture to the production of lateral spinal curvature I have set forth in *American Medicine*, April 8, 1905.

Briefly epitomized, this etiological factor arises from a bending of the head to the left, skewing of the paper, etc., in writing, in order that both eyes of the writer may have a clear view of the writing-field or space about the pen-point. And especially by the right or dominant eye, the one corresponding in function, and particularly in writing, with the right-handedness (expertness) of the right-handed person. This canting of the head to the left produces a functional cervical curve with the convexity to the right, which I suggest is the primary factor in the formation of subsequent compensation curves of the spine below. Orthopedists seem to have forgotten that the cervical vertebræ are part of the spinal column; any lateral bending of any part of the column produces twisting or rotation, with the production of reverse or secondary curves later, in the effort at compensation. (Figs. 1, 2.) George Sand and all the advocates of vertical handwriting have persistently demanded *Ecriture droite, sur papier droit, corps droit* —vertical handwriting, on vertical paper, the body also vertical. Knowing what was and is intended by the words, not what literally is said, we may add that even this intended advice is impossible of execution. No right-handed person ever writes so, or could write so, *i.e.* if the paper (as supposed) is horizontal, placed squarely (not skewed) before the median line of the body, and the penholder held as instructed in the "correct position," *i.e.* with the upper end pointing toward the shoulder. No one ever wrote a line in this position, and simply because he could not see the letters he was making. And to write we must see the letters which are being formed. (Fig. 3.)

Details as to the Nine Factors of Malposture in Writing.—

1. The position of the head may be:

a. Perfectly erect, its long or vertical axis corresponding with the vertebral axis when the body is

Fig. 4.—The common but in the picture somewhat exaggerated writing malposture, method of holding the pen, skewing the paper, bending of body, torsion of head, etc., in order to gain a clearer view of the writing-field.

erect and accurately and squarely in front of the desk.

b. Canted or tilted to one side, to the left in the dextral, and in varying degrees.

c. Twisted on the vertical axis of the head and neck, to the right in writing, by the dextral.

d. Positions *a* and *c*, combined or mixed.
e. Positions *b* and *c* combined or mixed.
2. The posture of the body may be:
f. Erect, the lateral axis parallel with the front line of the desk.

Fig. 5.—The medieval copyists wrote with the paper pitched at a sharp angle.

g. Bent to the left (in the dextral) in varying degrees, the vertebral column being either straight or curved.
h. The spinal column twisted in varying degrees.
i. The right side of the body turned toward the desk or approximated to it more or less.
j. Varying combinations of the positions *g*, *h*, and *i*.

In practical and unconscious writing the positions of the head and postures of the body above enumerated under 1 and 2 may be and usually are mixed and interdependent, thus resulting in many modifications and variations.

3 and 4. The location and angling of the paper upon the desk may be:
k. In front of the face and squarely placed, *i.e.*, its lower border parallel with the front of the desk.
l. Askew, at varying angles to the left, but usually at an angle of about 35° with the desk front.
m. With the left hand border parallel with the desk front.
n. Opposite the right shoulder in head and body postures *a* and *f*, the lower border parallel with the desk front.

With the ordinary straight penholder and pen held as universally ordered, and the head and body in postures *a* and *f*, no ordinary human being can write, because the index finger and the pen necessarily come between the right eye and the pen-point. (Fig. 3.) Therefore, every writer immediately disobeys the teacher and varies one or all of the positions, postures, etc., so that the dominant eye has an unobstructed view of the writing field. (Fig. 4.) The most extreme position of the body and head I have ever seen was in a patient who had an enormous astigmatism, and who was compelled to bring the eyes almost to a level of the table, with extreme rotation of the head in order to bring the astigmatic axes into parallelism with the lines of the writing being executed. Position *n* of the paper is the only one that permits of the perfectly erect or hygienic postures of the head and body designated as *a* and *f*, because only under such conditions can the dominant eye have a clear view of the writing field.

5. But the difficulty of writing in these postures and conditions is greatly increased by the flat desk, and is almost done away with by an inclination of the desk leaf or writing board at an angle of 30°. The ink will still flow from the pen with the leaf at this angle, the position of the head and body made most comfortable and hygienic, and the unconscious tendency to bend the head and body is neutralized. The copyists and monks of medieval and Latin times learned this, as is illustrated by the annexed cut. (Fig. 5.) An added and highly important consideration is that by the 30° or 40° sloped desk leaf, the eyes are enabled to look off at the book or writing at nearly a horizontal line, instead of down upon it with the eyes nearly vertically over the letters. The traction on the inferior recti muscles of the eyes with the resultant unnatural position of the eyes, is a prolific source of eyestrain. It also compresses the chest, humps the back, interferes with the circulation of the neck, the supply of blood to the brain, and the flow of air in and out of the lungs in breathing. The inclination of the desk may be more pitched in reading than in writing.

6. The organizers, teachers, trustees, furniture makers, and parents have too often failed to notice that children differ in height from adults, differ from each other, and that they have a habit of growing. Even the most progressive in very recent years have not come to a thoroughgoing knowledge of these simple facts, and have not made the school desks and seats to conform accurately to them. What is now needed is mechanical constructions which will meet the differences of each child in an easy and perfect manner.

Fig. 6.—The usual writing posture. The body and head are bent to the left, the head in addition, rotated so that the chin is to the right; there is a cervical curve with the convexity to the right; the right side [illegible] angles to the vertical lines of the paper, *a a*; to lessen the strain upon the written letters to the right, or the slanted style of handwriting.

o. The child's feet must rest lightly and naturally upon the floor, with the knees bent at about a right angle, the body at the proper distance from the edge of the desk. This can be effected only by means of a seat that may be raised or depressed, and not attached to the floor.

p. The leaf of the desk, in addition to being inclined at an angle of about 30°, must be of a height which brings the printed book and writing paper at a distance of about 14 inches from the eyes.

q. The pedagogs have also usually failed to notice that in reading a book it may be placed opposite the median line of the body or face (in erect position), but that in writing the paper cannot be thus placed. Hence the frequent permission in writing to turn the right side of the body toward the desk. When the paper is placed opposite the right shoulder upon a sharply-inclined desk leaf of the proper height, the eyes can see the writing field without unnatural positions of the body and head.

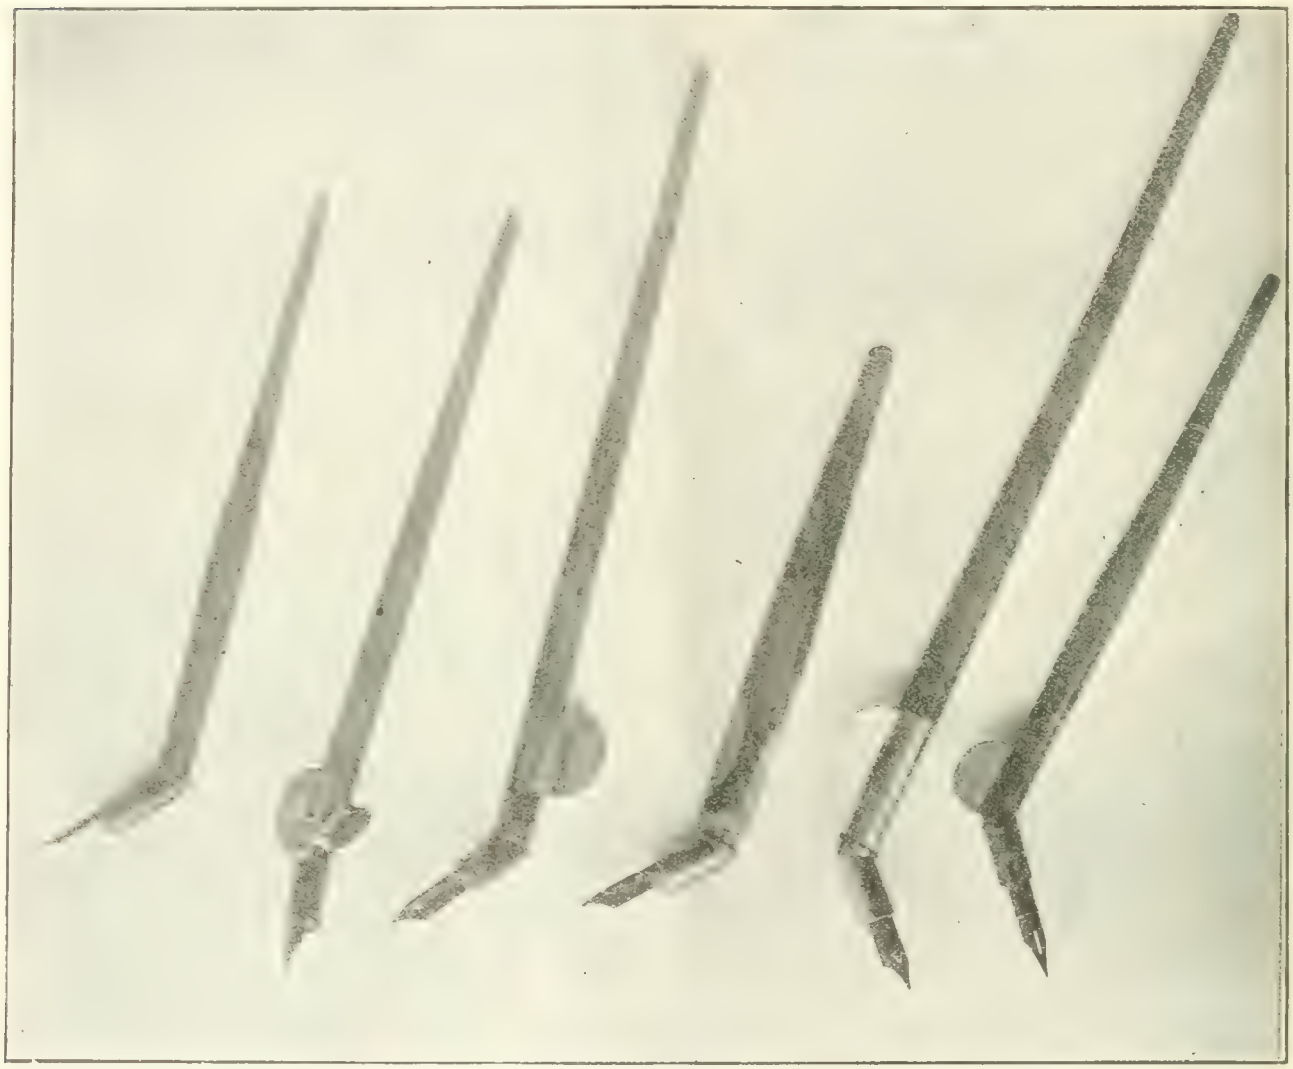

Fig. 7.—Styles of angled holders which permit of an unobstructed view of the writing-field without malposture of body, head, paper or hand.

7. Everyone has probably wondered why, when the school and writing teacher are ignored or forgotten, the pen and holder are either slanted differently; held between the first and second fingers; not seldomed angled parallel with the lateral lines of the paper, even nearly vertical, or toward the upright lines of the paper; drawn inward and toward the chest, the eyes above and looking down vertically upon the sheet; and the head in various other unnatural and cramping positions. (Fig. 6.) Such anomalies are too frequent to be called anomalies, and are simply the unconscious morbid methods whereby the dominant eye gets a free view of the writing field The types of this unhygienic pen-holding are too numerous and anomalous to be classified.

Artists, by means of long-handled brushes, etc., are able to gain a clear view of large spaces about the point of the brush, pencil, etc., by grasping the handle several inches from the point. They are thus under no necessity of inclining the head and body. Also their canvases, easels, etc., are either vertical or nearly so, and this does away with the visual difficulty encountered when the surface is horizontal or only slightly inclined. There is a simple method whereby the writing field or space about the pen-point may be seen without canting the head and body to the left and with the paper placed squarely in front of the body. This is by means of angled penholders which I have devised and of which I show cuts of some styles. (Figs. 7, 8.) The difficulty in holding these without the depression of the angled part is obviated by flanges or supports for the fingers. Of course they seem odd and "awkward" at first, but one soon writes with them easily and unconsciously. And with them one finds himself writing vertically without effort or intention. Any lateral or unhygienic posture is unnecessary in their use.

8. Some authors describe postures in which the body is leaned to the right, but they are not practiced because the writing-field is thus hidden to a greater degree. (Figs. 9, 10, 11, 12, 13, 14.) In all the multitude of improper postures, positions, pen holdings, etc., the teachers of writing, hygiene, and physiology have failed to notice that by some device nature will bring it about that the 90° axes of the eyes and astigmatism will be forced into parallelism with the vertical or slanted lines of the long letters being written. Hence the multiplicity of morbid postures begotten

by the failure to place the paper properly before the right shoulder and with the head and body erect, with the inclined desk leaf, and the penholder properly seized.

9. Only when these conditions last named are assured has the dominant eye an unobstructed view of

Fig. 8.—The writing-field is clearly seen with an angled holder, the body, head, and hand being hygienically posed, and the paper vertical and opposite the median line of the body, upon a flat desk or table.

the writing field, at the proper distances, etc. To secure this clear view of the writing-field with the paper placed according to universal instruction, the head and body are forced into unnatural positions. The unnaturalness and weariness of these morbid postures are lessened a little by the slanting of the letters to the right, and the tendency of the line of writing to slant upward. This any one can demonstrate by a few thoughtful tests or observations. And this is the source of slanted handwriting. (Fig. 6.) It is in fact a method of avoiding still more extreme torsion of the head or neck—a greater morbid slant of the patient by a slant of the writing.

I cannot find that anyone who has written of handwriting or of school hygiene, or who has constructed or advised as to the making of school desks and seats, has ever dreamed of the patent and easily recognized fact that every one of the nine factors are verities, and that they are bound together into a coordinate unity. None of them can be much changed without changing all of the others, and unconsciously every pupil and writer has solved the problem of carrying out the writing act by a special and personal adaptation and modification of each of the factors mentioned. The one all-dominating necessity which everyone discussing the subject seems to have overlooked, is that the writing-field (the space about the pen-point) shall be seen, seen with both eyes, but especially seen with the right eye. I speak of right-handed and right-eyed persons. All is reversed as to the left-handed and left-eyed. The essence of the matter is the necessity of binocularity and especially the existence of dextrocularity, a hitherto unrecognized thing, and the most intimate coordination of the right eye and right hand in the most mental and intellectual of all acts, except speech—that is, writing. The positions usually taught by school teachers, writing teachers, and copy-books are next to impossible, certainly not practised by the child or man when writing much or unconsciously. Then nature modifies all the nine factors mentioned, solely and simply in order that the hand, fingers, and pen shall not come between the right eye and the writing-field. The pathology of school life in a multitude of symptoms and diseases consists for the greater part in the unhygienic attempts to see the writing-field with the dominant eye. And the two great blunders of all the teachers and desk-makers are that the penholders and pens are not shaped so that the writing space or field about the pen-point can be seen with both eyes when the body and head are erect; or that the desk is not inclined at an angle of about 30°, and the writing paper is not placed squarely and opposite the right shoulder, with the body and head erect and squarely postured before the desk. With the paper so placed the desk top so inclined, the body and head thus erect, the right eye sees the paper at 12 inches or 14 inches, and the writing is vertical. (Figs. 15, 16.)

Probably as many as 200 distinct styles of school desks and chairs have been proposed, tried, and rejected, or in use. The reader may find some of these described in works on school hygiene, such as that of Kotelmann, Meyer, Staffel, Fahrner, Rettig, Hermann, Bendzula, Schildback, Schenk, Hippauf, Prausek, Wallraff, Barnard, Priestly Smith, Stone,[1] Shaw,[2] and especially Risley.[3]

So far as these relate to reading of a single book, the results reached by students of pedagogy are of great value—but with one exception: All advise an inclination of only 10° or 15°. It should be at least 30°, and with easily made devices for holding the book should be 45°. Even with the 30° inclination the pupil will often hold the book with the hand at a greater inclination, and there is no reason why every desk should not be inclined at least 30°. When two books are used at one time, or when the pen or pencil is used synchronously with reading, the inclination must be greater than 15°, in order to permit hygienic posture. In the writing act hygienic posture is almost impossible with less than a 30° pitch. This fact, together with insufficient space at the right, largely vitiates all previous results, decisions, and mechanisms as regards school-desks. The simple device needed is one which will permit a varying and independent pitch of the two vertical halves of the

Fig. 9.—A malposture pictured and described by authors, but never practiced by one in writing, because the writing-field would not be visible. The artist unconsciously shows the cervical curve with convexity to the right, almost always present in dextral writers.

desk itself. It should be possible to give either any pitch between 15° and 45°, and with devices so that the book, slate, paper pad, etc., will not fall, and may be held in place without the hand. If the pencil is used, even as high a pitch as 40° or 45° will be grate-

[1] *American Physical Education Review*, June, 1900.
[2] Ibid., June, 1901.
[3] Norris and Oliver: "Sustem of Disease of the Eye," Vol. II.

ful to the body and eye. If ink is used, the pitch should be at least 30°, as with this inclination the ink will still flow, and only with so high a pitch is there possible a view of the writing field with the right eye and at 14 inches distance, when the paper is placed

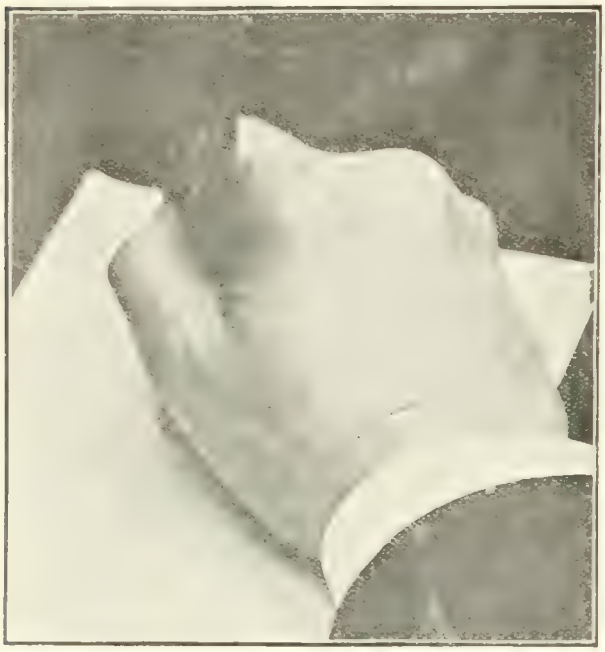

Fig. [illegible] skewing the paper to the right and bending the body and head to the right; it is never practiced because the writing-field is still more hidden than in the posture of Fig. 3 ordered as "correct."

opposite the right shoulder, with the head and body erect, without elevation of the right shoulder; this insures free motion of the right arm and hand in unconstrained and normal positions. (Fig. 16.) The copyists of the middle ages found this to be true, and our school teachers of former generations, who were their direct descendants, for a time kept up this wise tradition. The desk top should be made in two independent halves, the upper or farther edges so constructed that either may be raised, thus varying the pitch from the minimum of 30° to a maximum of 45° and thus adapted to reading or writing at pleasure. Thus made, the right-hand leaf would be the only one used for writing. All pupils should, of course, have desk and chair so adapted to their height that the book or paper would be at 14 inches from the eye when looking down upon it with a visual axis at an angle or inclination not greater than 150° or 155°. The visual axis at about 150° should approximately form a right angle with the inclination of the desk leaf at about 30°. (According to the oculist's trial frame, and as figured in illustration, the desk top would be at 145° and the visual axis at 35°.)

The Relation of Occidental and Oriental Writing Postures and Methods to Spinal Curvature.—In China and Japan the habits and methods of writing present throughout most noteworthy contrasts to those customary with us. The particulars may be briefly epitomized as follows:

1. The writing begins at the upper right-hand corner of the paper giving an evident advantage in seeing the writing field or letters which are being formed, and especially with the right or dominant eye.

2. The lines of writing are from the top to the bottom of the page, thus again securing increased visibility of the writing-field.

3. There is thus no need and no practice of skewing the paper to secure unimpeded vision of the writing-field. The writing is naturally vertical.

4. The writing brush (corresponding to our pen and holder), is grasped from two to four inches from the brush tip (corresponding to our pen); it is held usually between the second and third fingers (instead of between the thumb and first finger as with us), and either upright or slanting away from the writing space, to the right, and not, as our children are instructed, with the holder pointing toward the right shoulder. (Fig. 17.) Each one of the methods of holding the brush aids decidedly, and collectively very powerfully, in keeping the writing space clearly in view of the vision of both eyes. It seems almost as if all these methods were consciously designed that the writing-field might be seen.

5. In addition, Japanese and Chinese friends tell me it is a habit of many to hold the paper with the left hand, in the air, and pitched at an angle of from 30° to 50°. I did not know of this custom until months after I had written advising a pitch of the leaf of the writing desk of 30°. A greater pitch than this would sometimes not permit the ink to flow freely from our steel pens. The medieval copyists used a pitch of 50° or over, and our modern draughtsmen and artists often do the same. Modern artists in painting and sketching secure the clear view of the field of work by setting their canvas nearly vertical and by holding the brush or pencil from three to ten inches from the point. There are more modern writers than we suspect who increase the extent of visibility of the writing-field by holding the pen between the first and second fingers, or by grasping the holder two or three inches from the pen-point, by turning the hand half upward, or by slanting the penholder to the right. But these are devices forbidden by teachers (and writing books), who have no perception of the simple reason why the so-called "incorrect" habits and postures are unconsciously chosen.

6. Whether we should imitate the Oriental methods described above, either in part or not, is at present not my concern. Their result is our one great desideratum—the preservation of the erect and hygienic posture during the writing act. There is

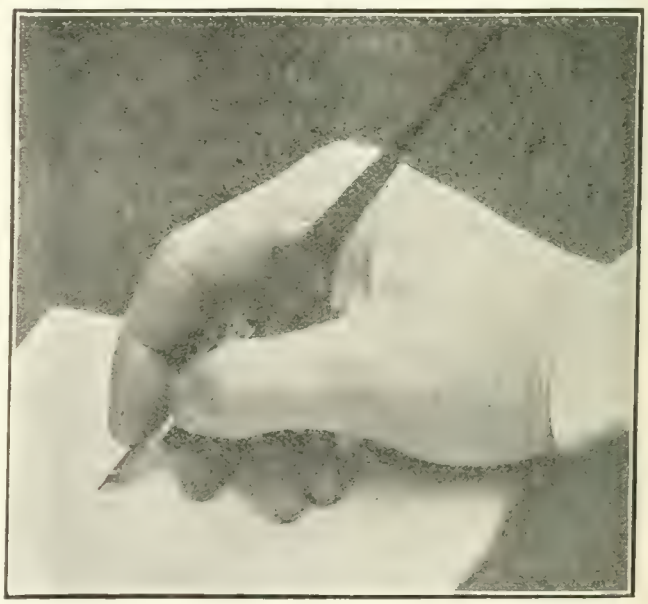

Fig. 11.—View of the writing-field as seen by the writer with skewed paper, and body and head turned to the left

little or no bending of the head to the left. If this functional right cervical curve, habitual in the Occidental posture, is the cause of the incipient spinal curves of our school children, it follows that there will be far less than 27 per cent. of Japanese

and Chinese children showing such curves between the ages of seven and fourteen years. An orthopedic examination of the backs of a large number of the children of Oriental schools would yield interesting and critical results. A minor query would be as to

Fig. 12.—To gain a better view of the writing-field the pupil instead of leaning to the left, sometimes bends forward until the eyes are directly above or even in advance, of the writing, lateral curvature and rotation being thus avoided.

the proportion of scoliotics among Occidental children blind from infancy.

That the approximation to the upright posture (not its absolute practice), lessens scoliosis, is apparently shown by the following statistics of examinations of school children:

	Slant writers per cent.	Vertical writers per cent.
Nurnberg	34	15
Zürich	32	12
Munich	24	15
Furth	65	31
Wurzburg	28	8

The first column averages 30 per cent., the second 16. But if the slanted style is accountable for twice as many scoliotics as the vertical, the vertical is still, apparently, responsible for one-half as many as the slant. It is, therefore, evident that the vertical style did not insure the vertical position of the head and body, or that some other cause is at work. If the true reason of malposition in writing had been understood, and the conception of its cure realized, the results and their suggestions would have differed and been of greater value. The above great differences found in different cities also exhibit an inexactitude which makes no one doubt the value of the methods employed.

The School Desk.—There is probably not a pupil's desk in the world constructed upon correct physiologic principles. Many approximate, but fail in one or more important particulars. This is because, with all of the interest, study, and invention which have been put into the work, with all that has been written concerning the vertical and slanted handwriting, there has been no understanding of the physiology of dextrality and dextrocularity, no comprehension of the optic problem which controls every posture and act. The wrong to the child began with the beginnings of pedagogy. Prior to this handwriting was usually vertical, because without a powerfully dominating necessity no adults, much less the shrewd monks, would have bent themselves to the left and skewed their vellum, tablet or paper at the absurd angle now common with all writers. But when school teaching began it was, of course, in the houses or rooms of adults, and with their tables, benches, forms or stools. No one then dreamed of the peculiar child nature, not even the size of the child's body. Hence, he sat upon a bench or seat too low, or what amounts to the same thing, at a table too high for the height of his body, and at about the level of his sternum, neck, or chin. When compelled to write he could do nothing at the desk, except by placing his forearm, and even his elbow, upon the table. Let an adult try to write sitting at a flat table the height of his neck and he will realize the child's predicament. With the arm upon the table there can be no writing accomplished unless the head is canted to the left, the body also, the paper placed askew, the feet or one foot thrust out to lessen the strain and wrenching of the spine, the pen held at a related abnormal angle, and the hand gripping the holder in a distorted way. (Fig. 4.) All this, that the right eye may have an unimpeded view of the space in which the letters are being formed. Think of the millions of morbidly raised right shoulders, the millions of necks and backs thus wrenched, with all the resultant disease, and during the last 400 years! And still going on!

Most school desks are without lateral space to the right in which the paper may be placed opposite the right shoulder when the body and head are erect and squarely placed in front of the desk, and not as now in front of the face or chest. This lack of lateral space to the right has always been the unrealized need, and upon securing it the complete establishing of the vertical style of handwriting will depend, as also the rescue of the child from the bad postures and ill-health caused by the diabolic head-tilting, right-shoulder-elevating, eye-ruining, body-bending, pelvis-cramping, spine-twisting, scoliosis-provoking postures, which have come down to our

Fig. 13.—The writing-field brought into clear view by holding the penholder between the first and second finger, thus lessening the need of bending the body or head to the left. The view is as the writer sees it, his head being out of the field in order to photograph the hand.

times. It will be useless to demand of the child that he shall write vertically, sit vertically, place the paper squarely and not askew, and opposite the median line of the body. No human being can write in that way unless the pen holder is held with the tip directed toward the northeast, or upper right corner of the paper (Fig. 14), or even toward the north, all sure to produce writer's cramp, or other

evil results in a short time.* In former times, as we know, the children were crowded together side by side so that it was impossible to place the paper opposite the right hand side of the body and keep the body and head erect. The high desk united to com-

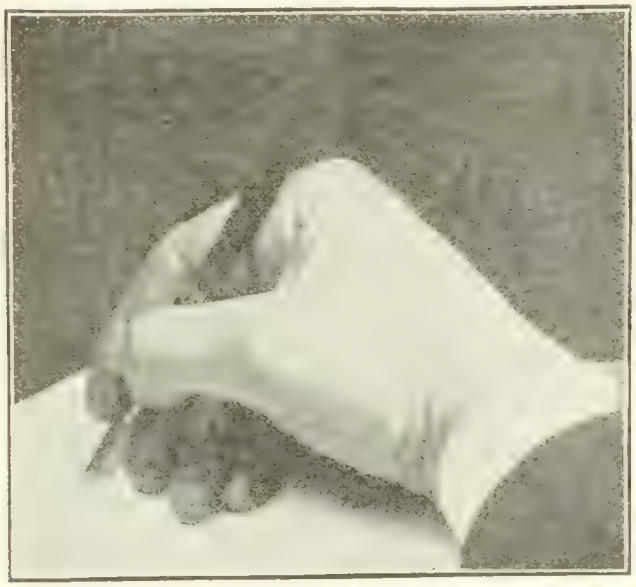

Fig. 14.—To secure a better view of the writing held the hand is held in a straining and unnatural position the holder directed 90° to the right of the right shoulder.

pel the arm to be rested upon the desk, the right side to be turned toward it, the left side away from it, the head and body bent to the left in order to gain a clear view of the writing space of the pen-point with the dominant eye. Even the flat desk or table coöperated to produce the resultant bad posture and the slanted chirography.

In all left-handed writers the foregoing factors and results are reversed, and the writing is back handed, or slanted to the left. (Fig. 18.)

There has also been much error in the statements made as to the history of slanted handwriting. The superb *History of the Art of Writing*, by Dr. Henry Smith Williams, gives an illuminating series of examples which show that the slanted handwriting appeared much earlier than has been supposed. Despite the high-pitched slope of the desks of the professional and more learned scribes, and also notwithstanding the dictation of the original vertical engraved, etched, or painted patterns, the slanted style appears throughout the Middle Ages, as the necessary result of the writing posture consequent upon the flat table, etc. Even in A. D. 93, the letters of a Greek MS. plainly lean to the right, and in a cursive Latin imperial rescript of the Fifth Century the slope is 15°. In a grant to the Church of Ravenna of the Seventh Century, the right oblique slant is 10° or more, and even in Magna Charta all letters lean to the right somewhat. Examples of similar slanting are found in the handwriting of Michael Angelo, Macchiavelli, Ariosto, Tasso, Luther, Shakespeare, Bacon, Lope de Vega, Milton, Locke, Leibnitz, Johnson, etc. Montaigne, Spencer, Galileo, Corneille, Addison, Pope, Newton, Voltaire slanted their letters to about the same extent as is now customary. Dante, Piers, Ploughman, and others, wrote the vertical hand. Goethe leaned his letters extremely, Schiller less so, while Tennyson's were nearly vertical. Thackeray's were absolutely upright. Of the signers of the American Declaration, only one is in vertical letters. Longfellow wrote a "backhand," and in a MS. of the Tenth Century the letters also lean to the left, as do MSS. of Henry II, and Richard I. In King John's Charter the letters are generally upright, although many letters slant to the left, especially lower case *d*, and capital *D*. Of course the best writers and penmen were usually intelligent, and wrote more nearly correctly, *i.e.* vertically, while the writers of the lower and commercial classes illustrate the degeneracy which quickly overcame the cursive style of writing. In general, the older and more important styles of headings, those in capitals, etc., were upright, while the less important and the body of the writing showed the inevitable leaning that came with crowding, and cursive writing. An instance of this is our own Declaration of Independence, a few lines of which next to each other I reproduce. (Fig. 19.)

Malposture Not the Cause of Myopia.—In almost al the discussion as to school desks, especially that originating in Europe, there is much said about the influence of malposture in producing myopia, and it is largely twaddle. The tremendous gathering of statistics and the thoughtless ascription of the truly tragic increase of myopia to malposture in study and

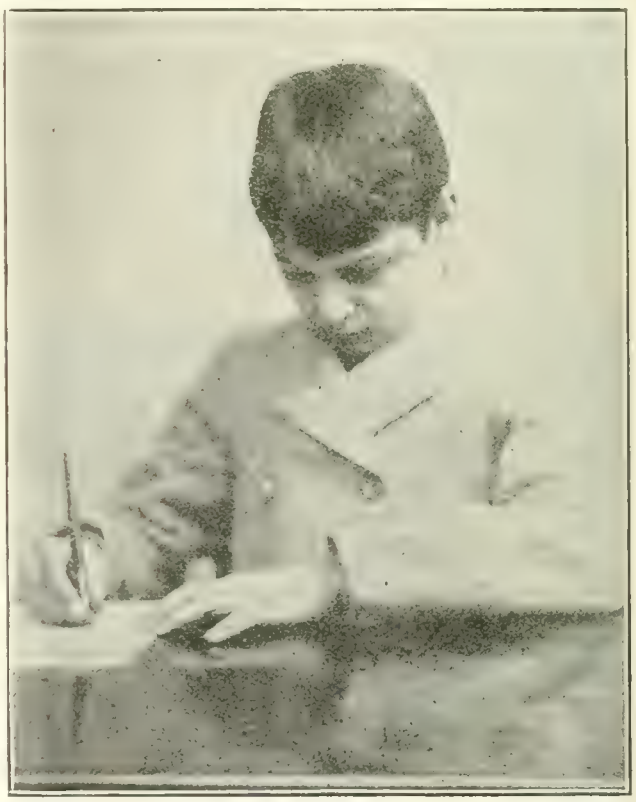

Fig. 15.—The normal or hygenic posture of the body and head with the paper placed vertically and opposite the right shoulder. The arm and head thus have free motion. There is some constraint, due to the flat desk, a too great distance of the writing, and the fact that the visual axes, falling at an angle of about 45°, demand a bending of the head forwards, or too great traction on the depressor muscles of the eyes.

writing are essentially wide of the mark. Some accidental, incidental, and subordinate influence is, indeed, to be ascribed to the malposture criticised. Kotelmann's pages concerning myopia are, for instance, wholly misleading, and utterly ignore the real cause—which is the noncorrection of ametropia, and especially of astigmatism. In Germany, the motherland of myopia, there is no scientific correction of

* Some time after these words were in type, a striking confirmation was found in an article published without any knowledge of my work. I quote the paragraph:

"One thing, however, has been much impressed upon me, and that is that those who are normally left-handed and are taught to write with their right hand, suffer from writer's cramp much more readily than normally right-handed individuals. It would seem as though nature were taking her revenge for an interference with her original plan, for the man is right-brained and should not be compelled to use his right hand for a work requiring so much coordination as does writing." ("Some So-called Rheumatisms," J. J. Walsh, *Medical News*, February 18, 1905.)

ametropia. The very simplest and most fundamental conditions of accuracy are wilfully or ignorantly unnoticed, and the ocular, nervous, and nutritional systems are hopelessly ruined and by wholesale. With one splendid exception our American students

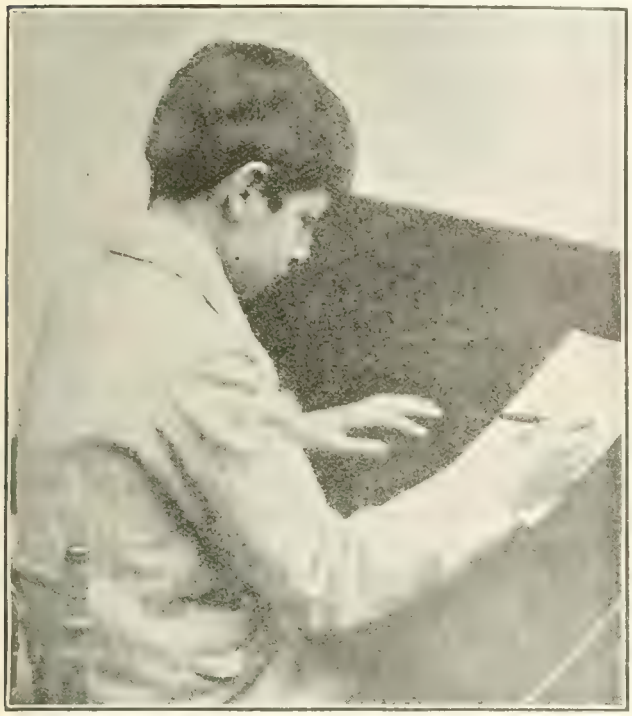

Fig. 16.—[illegible] posture is hygienically perfect and the faults [illegible] avoided.

of the subject have usually adopted the European blunder, and for a hundred years we shall doubtless have the empty echoings of the European nonsense as to school desks and myopia.

In an article (published in the *Klin. Monatsbl. f. Augenheilkunde*, July, 1904, and translated in the *Annals of Ophthalmology*, January, 1905), Dr. Liebreich lends his authority to the error that myopia is caused by the combined action of too strong convergence and too great an accommodation tension, quoting the investigations of Cohen, Hersing, Seggel, and others. This inversion of cause and effect does not prevent the true statement that "through the too near approach of the head to the table, the normal curvature of the spinal column is increased and by simultaneous rotation of the head and body lateral curvature ensues." Of course, all such statements and explanations miss the causes of the cause which are the action of astigmatism in producing myopia, its effect in compelling parallelism of the axes of the astigmatism and of the written lines on the paper, and the more fundamental necessity of binocular vision of the writing-field. Scholder also says that myopia is produced by getting the eyes too near the paper, because, he says, the more the head and body are depressed and thus myopia is produced. But what is the *causa causans* he never asks. Why [illegible] ing of the paper? In Scholder's table of the increase of scoliotics in the grades of the Lausanne schools he notes in an added column the increase of myopia, as follows:

	Scoliotics per cent.	Myopia
First grade	[illegible]	[illegible]
Second grade	[illegible]	[illegible]
Third grade	[illegible]	[illegible]
Fourth grade	[illegible]	[illegible]
Fifth grade	28.3	
Sixth grade	[illegible]	[illegible]
Seventh grade	31.	

If the author had scrutinizingly asked himself why the increase of scoliosis is suddenly stopped and decreased at about 14 years of age, and why the rate of myopia at the same time is suddenly increased, he might have seen a suggestion of the cause of myopia. In Dr. S. D. Risley's magnificent article (Norris and Oliver: "System of Diseases of the Eye," Vol. II.) there is a clear understanding and statement of the problem of myopia. Myopia is not due to the bad desk and bad posture, but to the bad or absent spectacles. (I differ from Dr. Risley in one minor point—the astigmatism is not only "the turnstile," but the path, road, and continuance of the road itself, which leads to the bog of myopia.) If every school trustee, pedagog, physician, and hygienist would read every word of Dr. Risley's article five times a year, one of the greatest afflictions of mankind might be obviated. Unfortunately, it is buried from all but ophthalmologists, and the majority of these care too little for this revolutionizing truth.

The remarkable success of all the European investigations in not seeing the cause of myopia is a painful illustrations of the difficulties in the way of scientific and medical progress. Jaeger, Ely, and Horstmann were approaching the true explanation, in their work leading to the measurements of the anteroposterior diameter of hyperopic and myopic eyes; by Arlt and Donders, the latter emphasizing the rôle of predisposition—that easy, old and still popular word to cover ignorance of the real and active pathogenic factor. Dobrowoesky and Erisman charged the accommodation with the production of myopia, while Förster though it was due to convergence. Mauthner ascribes the leading rôle to spasm of the ciliary muscles, while Stilling threw the responsibility upon the obliques and the shape of the orbit—a view opposed by Schmidt-Rimpler and Seggel. Hasner and Weiss contended that myopia is caused by a too short optic nerve, and Schnabel and Herrnheiser by a lessened resistance of the sclerotic. It remained for an American oculist to discover the true etiology which is to-day as much ignored by European oculists and school hygienists as if it had been made this morning instead of 38 years ago. In 1867, and again in 1871, Dr. John Green of St. Louis set forth the explana-

Fig. 17.—[illegible]

tion, and a few years later Dr. S. D. Risley of Philadelphia demonstrated it by studies of school childrens' eyes in epoch-making papers, which, within the next generation or two may begin to make the epoch.

The Evils of Eyestrain.—In all of the foregoing there have been considered only the children, students, and writers who had eyes so near normality as regards ametropia that they had no severe eyestrain or morbid reflexes from use of the eyes in a

Fig. 10.—All [illegible] writers and this [illegible] writing by [illegible]

natural way, or even in the unnatural ways begotten by morbid postures; but unnatural posture produces unnatural ocular function, and besides this, from 25 per cent. to 50 per cent. of all civilized persons have eyestrain or hurtful use of ametropic eyes. The amount of harm done the eyes, the neurologic mechanism, the digestive and assimilative systems depends upon three things: the kind and the degree of the ametropia; the amount of reading, and especially of writing, done; the susceptibility of the patient, the general vitality, intercurrent diseases, etc. It has been found that from 50 per cent. to 64 per cent. of school children are sickly or below a desirable norm of health. I do not think it is an exaggeration to say that the ills of 50 per cent. of these hygienicly subnormal children and students are due to the morbid postures compelled by the present false methods of writing and reading. Of the remaining 50 per cent., a full half are directly caused by the eyestain of ametropic eyes. Headache, "weak eyes," migraine, anorexia, dyspepsia, and many types of denutrition, spinal curvature, insomnia, "nervousness," many cases of chorea and epilepsy, despondency and frequent psychic disorders, truancy, immorality, etc., almost any form or kind of functional disease—all these, and the denutrition that fallows the ground for the incoming of infectious and terminal diseases—all of these are, or may be, the clear consequences of eyestrain. Only proper and scientific spectacles can extinguish these evils. But without glasses they are tremendously increased and intensified by the morbidities of posture engendered by the present school desks and methods of writing and reading. A revolution is demanded by an enlightened hygiene in school furniture and methods of writing and study. It is the most profound and crying reform of the day, a matter of national and evolutional importance almost overtopping all others.

Read the clinical biographies of the great sufferers from eyestrain, and note how intolerable and impossible writing becomes. A thousand quotations from their biographies and letters might be made showing that suffering of the most varied and subtle kinds follows directly upon use of the eyes especially

in writing, and is at once relieved with cessation of writing and reading. The abnormal and morbid postures caused by nonunderstanding of the optic problems in writing add enormously to the preexisting and attendant eyestrain.

SIMPLE ULCER OF THE STOMACH AND ITS SURGICAL TREATMENT.*

By JOHN J. McGRATH, M.D.,

NEW YORK.

PROFESSOR OF SURGICAL ANATOMY AND OPERATIVE SURGERY AT THE NEW YORK POST GRADUATE SCHOOL; SURGEON TO POST GRADUATE, HARLEM, AND COLUMBUS HOSPITALS.

SIMPLE ulcer of the stomach is not an uncommon disease. Berthold found it or unmistakable evidence of its having been present in 2.7 per cent. of his autopsies. According to v. Jaksch, in 11,888 autopsies performed in Prague there were found 164, or 1.4 per cent., with open ulcer, and 373, or 3.1 per cent., showing the cicatrices of healed ulcers, a proportion of open ulcers to healed ulcers of 1 to 2¼. Grünfeld of Copenhagen in 1,150 autopsies found ulcers in 124 bodies, or 11 per cent. of the entire number. Grünfeld's patients, however, were all over fifty years of age. Probably 5 per cent. of all people, children excluded, that come to autopsy have or have had ulcer of the stomach. Welch estimates that for every one case of open ulcer found at autopsy there are three that show scars of healed ulcers.

Ulcer of the stomach is more common among the people of some countries than those of others. It is more frequently encountered in women than men, two to one or, according to some observers, four to one. It is found most frequently between the ages of 25 and 35 years in women, and 30 and 45 in men. It is rarely met with in children under 10 years of age.

*Read at the annual meeting of the Windom and Franklin Counties and Connecticut Valley Medical Associations, Brattleboro, Vermont, September 27, 1904.

Gastric ulcer is caused by the action of the gastric juice upon a portion of the wall of the stomach that has lost to a sufficient degree its power of resistance. The active principle in the gastric juice is the hydrochloric acid; the element of resistance in the stomach wall is the normal alkaline blood circulating in and thoroughly saturating all the tissues that are exposed to the action of the gastric juice. When the circulation ceases in death the gastric juice immediately attacks the wall of the stomach. During life gastric ulcers occur only in those parts which are exposed to the influence of the gastric juice. Very frequently there is found associated with gastric ulcer an excess of free hydrochloric acid, but that the excess of hydrochloric acid cannot of itself produce an ulcer is shown by the fact that there are many cases of persistent hyperchlorhydria without there being any such lesion formed. The additional etiological factor concerned is to be sought in the diminished power of resistance upon the part of the tissues of the stomach wall, and apparently it is always associated with a temporary or permanent diminution or cessation of the circulation in the affected area. It will also be observed in many cases that the individual ulcer corresponds to the limited area supplied by a definite vascular branch. The interference with the circulation may be due to various causes: spasmodic contraction of small arteries which may be, in turn, dependent upon nervous vasomotor influences; thrombosis or embolism of small vessels; changes in the walls of small vessels, obliterating endarteritis, etc.

A condition of marked anemia is often found associated with ulcer of the stomach, and is, no doubt, in many instances due to the repeated hemorrhages from the ulcer; in some cases, however, the anemia precedes the ulcer formation and may then be of etiological significance, in that, as a result of the anemia, the power of resistance is diminished and the tissues of the stomach thus more easily succumb to the action of the gastric juice. The quantity of hydrochloric acid is often found increased in anemic patients, and it is said that the alkalinity of the blood may be diminished.

Gastric ulcer is found only in those parts of the alimentary canal with which the gastric juice comes in contact, the lower part of the esophagus, the stomach, first part of the duodenum, and where a gastrojejunostomy has been established a typical ulcer may be developed in the attached coil of intestine. The ulcers as a rule, show but little tendency to heal and may persist for many years. The location of the ulcer varies. According to Welch's figures, the ulcer is situated upon the lesser curvature in 36.3 per cent.; the posterior wall in 29.6 per cent.; at the pylorus in 12 per cent.; upon the anterior wall in 8.7 per cent.; at the cardiac end in 6.3 per cent.; at the fundus in 3.7 per cent., and upon the greater curvature in 3.4 per cent. The great majority of all are situated in the pyloric portion of the stomach. The ulcers are usually single, in about 20 per cent. of the cases they are multiple. Rarely there may be three or four or even more present, or several may be fused together. They may be quite small, but usually they vary in size from a pea to a silver quarter or even larger up to a diameter of several inches. As a rule they are round or oval in shape, having a punched-out appearance and with edges sharply defined. They vary in depth, some extending only part way through the mucosa and others deep, through the entire thickness of the stomach wall or even into adjacent organs that have in the meantime become adherent. The deep ulcers are usually funnel-shaped, the diameter becoming progressively shorter the deeper the ulcer penetrates. The base of the ulcer is, as a rule, clean and smooth. In recent cases the margins are not indurated nor raised. Old ulcers are accompanied by a chronic plastic inflammation that affects the base of the ulcer and the immediately adjacent portion of the stomach wall with the result that the base and margins become thickened and dense and the edges everted, and the lesion may thus present a very close resemblance, macroscopically, to a malignant ulcer.

As a rule the mucous membrane of the stomach, except in immediate proximity to the ulcerated area, is found in a normal, healthy condition, and this in marked contrast to the changes that affect the entire gastric mucous membrane in cancer. Simple gastric ulcer is essentially a local lesion.

The pylorus, even if not actually involved in the ulcerative process is usually found contracted. This contraction is due to muscular spasm, is reflex in character, and is accompanied by hypertrophy of the muscular elements that make up the pyloric ring. If the pylorus is involved in the ulcerative process or is the site of a cicatrized ulcer the stenosis of the pylorus is then due to the changes in and about the ulcer as well as to the muscular spasm. As a result of the stenosis of the pylorus the stomach may gradually become dilated.

As the ulcerative process gradually extends deeper through the stomach wall a localized peritonitis is set up with the formation of adhesions between the stomach and adjacent organs, pancreas, liver, spleen, gall-bladder, colon, duodenum, or the diaphragm or anterior abdominal wall.

Hemorrhage occurs in a large proportion of the cases. The quantity of blood lost at each hemorrhage may be slight, or a profuse, fatal hemorrhage may occur as the result of erosion of one of the larger arterial or venous branches. The ulcer may heal spontaneously and may remain healed. This is the outcome in probably 75 per cent. of the cases. If the ulcer has been superficial, only part way through the mucous membrane, the healing is accomplished with reproduction of the normal mucous membrane; if the ulceration has been deep, through the entire mucous membrane or deeper, then the destroyed tissue is replaced by new connective or scar-tissue. The connective tissue found in and about the ulcer or cicatrix has a strong tendency to contract, with the result that the stomach becomes distorted. If the pylorus is affected this orifice becomes stenosed and narrowed and the stomach secondarily dilated. If the body of the stomach has been involved and the ulceration has been extensive, a condition of hour-glass contraction may be produced, the constricted portion or isthmus being so narrow as to offer serious obstruction to the proper evacuation of the stomach. Contraction of a healed ulcer about the cardiac orifice or in the lower end of the esophagus may cause obstruction in this situation and interfere with the passage of the food into the stomach.

An ulcer may reappear in the site of a previous ulcer or may attack a new area. Carcinoma may develop in an unhealed ulcer or in the scar of an ulcer that has healed. According to Talma, this direful termination or change occurs in from 6 to 13 per cent. of the cases.

The ulcer may perforate through the entire thickness of the wall of the stomach. This process may be gradual and be preceded by a circumscribed peritonitis and the formation of protecting adhesions, and as a result of the perforation we may have the formation of a circumscribed abscess. This process of gradual perforation usually affects ulcers of the posterior wall and the resulting abscess may be of

the so-called subphrenic variety or the suppurative process may extend to the liver, spleen, pancreas, etc. Perforation may occur through the adherent diaphragm into the pleural cavity or pericardium or into the adjoining hollow viscera, colon, duodenum, or through the abdominal wall. If protecting adhesions are not present or are not sufficiently firm and extensive at the time that perforation takes place, then the stomach contents may escape into the free peritoneal cavity, and a general peritoneal infection may be thus set up. Ulceration into the free peritoneal cavity occurs as a rule in connection with ulcers of the anterior wall and near the cardiac end of the stomach.

Gastric ulcer may run an acute or chronic course clinically. The acute course is seen more frequently in young anemic females. Gastric ulcer may exist for a long time without giving rise to any characteristic symptoms and may thus fail to be recognized. Unmistakable signs of ulcer have been found at autopsy in patients who have not complained of any gastric symptoms during life. The first positive symptoms of the existence of a serious affection of the stomach that appear may be those of perforation or severe hemorrhage or of carcinoma. In most cases, however, characteristic symptoms pointing to the disease manifest themselves early, and these are pain, hemorrhage, and vomiting. The degree to which the general health is affected depends upon the severity of the symptoms.

The pain is the most constant symptom. It is usually described as a steady burning or gnawing pain situated in the epigastrium, or may be referred to the lower dorsal region to the left of the vertebral column. In some cases the pain is not very severe—the patients complain of a dull pain or feeling of distress. The pain comes on soon after the ingestion of food, becoming gradually more and more severe, and continues until the stomach has emptied itself either by discharging its contents into the duodenum, or else by vomiting. The pain is markedly increased by pressure in the epigastrium, or at times by pressure in the back to the left of the lower dorsal vertebra. The pain varies with the character of the food—soft or liquid food or a light diet are accompanied by less pain. Occasionally we meet patients who say that the pain is relieved temporarily by the ingestion of food—milk, eggs, etc. The food serves to neutralize the acid in the gastric juice, and in this way relieves for the time being the discomfort.

Probably every case of ulcer of the stomach is accompanied by more or less hemorrhage. The hemorrhages may be slight and only sufficient to stain the vomitus, or the blood may escape into the intestine and pass unrecognized in the feces. The hemorrhages may be oft repeated, or may only occur at long intervals. Hemorrhage may be a prominent symptom, and occur with such frequency and be so profuse as to reduce the patient to a condition of extreme anemia. Hemorrhage due to the erosion of a large arterial branch may continue uninterruptedly until the patient succumbs. Most frequently the blood is vomited. From 50 to 80 per cent. of the patients vomit blood in greater or less quantity during the course of the disease. Most frequently the hematemesis occurs after a meal. The patient complains of a feeling of discomfort, faintness, nausea, and vomits a large quantity of blood, red and nearly pure, or brownish and mixed with the food. Severe hemorrhage may occur without the blood being vomited, the blood in this case escaping from the stomach into the intestine. Under these conditions the diagnosis of hemorrhage must be made from the general signs of loss of blood. The blood which is lost in this way may be recognized in the stools by their black, tarry appearance (melena). In minute quantities blood may be detected in the feces by proper chemical tests (Boas).

Probably 3 per cent. of all patients who suffer from ulcer of the stomach die of hemorrhage. Of a series of 270 fatal cases of gastric ulcer examined post mortem, it was found that 27 (10 per cent.) had died from hemorrhage. Fenwick reports that of 112 fatal cases of gastric ulcer 16 per cent. had died from hemorrhage, and in a second series of 298 fatal cases, in 56, or nearly 19 per cent. death resulted from hemorrhage. Fatal hemorrhage is more frequently seen in the chronic cases. In the acute cases the bleeding usually ceases spontaneously. Rodman says that 8 per cent. of all patients who suffer from hematemesis die of hemorrhage. Welch estimates that hemorrhage is the cause of death in from 3 to 5 per cent. of all cases of gastric ulcer.

Vomiting is usually a prominent symptom. The vomiting is due to the irritability of the stomach, or to its inability to empty itself either on account of the pyloric stenosis, or because of a condition of hour-glass contraction. Even if the ulcer is situated at a distance from the pylorus, obstruction may be offered at this situation on account of the reflex spasm of the muscular elements that comprise the pyloric ring. Vomiting usually occurs soon after the ingestion of food, and is followed by relief of the pain and distress. Sometimes the vomiting occurs independently of meals, may be during the night or early morning, and the vomitus may then consist of almost pure gastric juice. Vomiting at long intervals and in considerable quantity is usually associated with dilated stomach. When the vomiting is a prominent feature the emaciation may become very pronounced. The material vomited often shows the presence of blood. It may be blood-stained or abundantly admixed with blood, or in the event of copious hemorrhage may even be pure blood. The material vomited usually tastes sour unless ejected immediately after being ingested, and shows excess of free hydrochloric acid in contradistinction to the vomitus of cancer.

Examination of an Ewald test breakfast will usually show the same excess of hydrochloric acid. It is not desirable to use the stomach tube in those cases where the diagnosis is patent; still if used with proper caution the employment of the stomach tube is not absolutely counterindicated.

The appetite usually remains good, but patients do not eat on account of fear of pain, etc.

Constipation is commonly found associated with gastric ulcer.

Amenorrhea is often present on account of the condition of anemia that is usually present.

Physical Examination.—If the stomach is dilated there may be observed a bulging or prominence of the abdomen corresponding to the position occupied by the dilated stomach. A circumscribed area of tenderness more marked on pressure is usually found in the epigastric region below the ensiform process. Another area of tenderness may be found in the back to the left of the lower dorsal vertebræ. If the adhesions between the stomach and adjacent parts—especially liver and abdominal wall—are dense, it may be possible by palpation to detect a tumor. As a rule no tumor can be felt; where a palpable tumor is present the condition is likely to be one of carcinoma.

Perforation of a gastric ulcer is a serious accident. If protecting adhesions have been formed there will be produced, as a result of the perforation, a cir-

cumscribed abscess; if no adhesions have been formed the escape of material from the stomach into the free peritoneal cavity will set up a general peritoneal infection which almost invariably proves fatal. Perforation may occur abruptly in patients who have complained of few or no symptoms of gastric ulcer and who have not considered themselves sufficiently ill to consult a physician. Perforation into the free peritoneal cavity is marked by a sudden sharp pain referred to the epigastrium and associated with signs of shock gradually merging into those of a general peritonitis. Perforation occurs in about 6½ per cent. of all cases of ulcer.

Among the more immediate complications of gastric ulcer may be mentioned cicatricial stenosis of the pylorus with consequent dilatation of the stomach; hour-glass contraction; perigastric adhesions; severe hemorrhage; perforation.

As more remote complications we may have a condition of pronounced anemia, pulmonary tuberculosis, or malignant changes in the ulcer or cicatrix.

The prospect of cure is certainly greater, and the likelihood of a fatal termination from hemorrhage less in those cases of gastric ulcer seen in young anemic females than in those seen in older women and in men. According to Ewald the mortality is greatest in patients between 40 and 60 years of age.

Debove and Rémond, quoted by Einhorn, estimating from a large number of cases, give but 50 per cent. of permanent cures, and Leube admits a mortality of 25 per cent. Riegel places the mortality at 8 to 10 per cent.; Lebert, 10 per cent.; Welch, 15 per cent. Fenwick says that about 4 cases out of 5 heal spontaneously according to the proportion of scars to open ulcers found at autopsy, a mortality of 20 per cent. In figuring the percentage of cures from a clinical standpoint, it should be remembered that improvement or cessation of symptoms does not necessarily mean actual cure. Some of these patients are only apparently cured, and later may die from hemorrhage, perforation, cancer.

According to the estimate of Welch for every one patient seen at autopsy with open ulcer there are three who exhibit the scars of healed ulcers. If these figures might be used they would indicate 75 per cent. of cures either spontaneous or as the result of medical treatment. Of course some of the healed ulcers might be overlooked at autopsy, or having been superficial would leave no scar, and thus the percentage of cures might be underestimated.

Death may be directly attributed to hemorrhage in 3 to 5 per cent., and to perforation, according to Welch, in 6½ per cent., and according to Debove and Rémond, in 13 per cent. Many of the patients who suffer from gastric ulcer develop cancer, tuberculosis, anemia, etc. It is said that 20 per cent. of persons who suffer from gastric ulcer develop pulmonary tuberculosis, and the number in whom the ulcer undergoes malignant changes has been placed as high as 13 per cent. Bulstrode investigated 500 cases of gastric ulcer that were admitted to the London hospital from 1897 to 1902. There were 89 deaths, a mortality of about 18 per cent., 10 per cent. dying from peritonitis due to perforation, 2½ per cent. from hemorrhage, and 5½ per cent. from other causes associated with the disease; 82 per cent. were discharged from the hospital apparently cured or greatly improved. As to the question of recurrence after apparent cure or marked improvement, Bulstrode discovered that of the 500 cases, 211, or 42 per cent., had had previous similar attacks; of these 211 cases 116 had had one previous attack, 41, two; 15, three, and 39 four [illegible] attacks.

Treatment.—Without question the treatment of ulcer of the stomach during its early stages and in the absence of accidents and serious complications should be medical. Cases of so-called acute ulcer occurring in young anemic females are more amenable to medical treatment than those seen in older women and in men. They are not likely to die from hemorrhage, but upon the other hand the ulcers are not unlikely to perforate and set up an acute peritoneal infection.

As to the question of surgical interference as routine treatment, if it can be shown that the mortality after operative treatment of ulcer of the stomach is considerably less than when non-operative measures are employed then the warrant for operative interference is established. It is difficult to obtain figures that give the exact rate of mortality of those cases of ulcer of the stomach that are treated medically, but from the figures and facts enumerated in the preceding paragraphs it would appear to be reasonable to assume a death rate of 25 per cent. for all cases thus treated. This percentage is probably not too large, especially if we include the deaths that result from the more remote sequelæ and if we omit the acute cases that occur in young anemic females and which usually respond to internal medication, diet, etc., and for which the question of surgical interference hardly presents itself except in the event of some serious accident, for example, perforation.

As to the mortality following surgical treatment, we have the figures of Rodman, who collected 40 cases where radical operations, pylorectomy, gastrectomy, and excision of the ulcer were performed, with six deaths—a mortality of only 15 per cent. Robson collected 188 cases of chronic ulcer treated by operation, excision, pylorectomy, pyloroplasty, gastroenterostomy, etc. ,with 31 deaths, a mortality of 16.4 per cent. Of his personal cases there were 34 with six deaths, a mortality of 17.6 per cent. Heydenreich places the mortality after operation for simple ulcer at 16.2 per cent. as against 25 and 30 per cent. following non-operative treatment, and upon these figures he recommends operation as being less dangerous than the disease itself. Moullin reports 15 cases of operation for simple ulcer, with two deaths—about 13 per cent. In nearly all of Moullin's cases the operations were radical in their scope, excision of the ulcer in 12 cases. In two cases gastroenterostomy was the operation performed.

In nearly all the cases considered in the foregoing paragraphs the operations performed were of a radical nature and of themselves a severe tax upon the strength of the patients. In many instances the patients were already seriously reduced in health and vitality when operation was proposed, and in some cases the operation was performed in extreme emergency, for perforation, etc. In spite of these unfavorable conditions, however, the mortality is less than 18 per cent., really less than the death rate observed in those cases where the treatment was strictly non-operative. If we now study the mortality following gastroenterostomy for simple ulcer of the stomach we will find it to be much less than where a radical operation is performed. Robson shows a mortality after gastroenterostomy of only 4 per cent. in all cases, good and bad, malignant and simple, and Moynihan reports a series of 50 cases of gastroenterostomy for ulcer with but a single death.

Gastroenterostomy for simple ulcer is curative in its effect, and when properly performed by com-

petent surgeons and upon patients not too greatly reduced through inanition and hemorrhage, should be almost devoid of fatalities. Let us hope that the intractable, obstinate, and persistent cases of gastric ulcer will come into the hands of the surgeon while there is still good promise of cure without undue risk of a fatal issue. Operation in these cases is undertaken with the double purpose of relieving the harassing symptoms and of preventing or forestalling the occurrence of the oft fatal complications and sequelæ.

Operation is imperatively indicated in cases of profuse and recurring hemorrhage where the ordinary non-operative measures fail to control the bleeding, especially in older females and in men (chronic ulcer); likewise in the event of perforation into the peritoneal cavity. It may become necessary to resort to operative measures for the relief of some of the more remote complications such as adhesions that fix the stomach to the abdominal walls or adjacent viscera, subphrenic abscess, etc.

Operation for gastric ulcer, aside from its complications, etc., may be either palliative or radical in its scope.

Palliative Measures.—Although the procedures considered under this head are palliative in their immediate effect, still they are indirectly curative in that they provide a sufficiently free outlet, so as to permit of the prompt evacuation of the stomach, and thus allow of longer intervals of physiological rest to the affected organ, and, further, by diverting the food current away from the raw, ulcerated areas, they relieve these parts of irritation and give them an opportunity to heal.

For Hourglass Contraction.—The hourglass stomach is caused by the contraction of the cicatricial tissue that is formed in and about an ulcer that affects the body of the organ. The stomach may thus be more or less completely divided into two or even three pouches, the pouches communicating with each other through narrow channels that may be so contracted as to barely permit the introduction of a finger. Under these circumstances the stomach contents can only be forced with difficulty from one pouch through the narrow ulcerated passage into the next pouch; thus the food stuffs are likely to remain for an unduly long period in the stomach, become stagnant and act as an almost continuous source of irritation to the ulcerated area, and in this way retard the healing process.

The remedy for this condition is to enlarge the passage or neck between the pouches—gastroplasty—or else to make an additional communication between the pouches—gastrogastrostomy—or, finally, to establish an anastomosis between the first (or proximal pouch) and the small intestine—a gastroenterostomy. Even in those cases where a gastroplasty or a gastrogastrostomy has been performed to correct the hourglass condition, it is often advantageous to establish a gastrojejunostomy in addition. As to the choice between gastroplasty and gastrogastrostomy, the former has several disadvantages as compared with the latter. In the first place, the field of operation, for incision, sutures, etc., is the thickened ulcerated area itself, and in the second place, even if an opening of sufficient size is obtained, if the ulcerative process is still active the stomach contents in passing from one pouch into the other must still come in contact with the raw surfaces and thus keep up the irritation and interfere with the healing process.

For Pyloric Stenosis.—In order to overcome the obstruction offered by a contracted ulcerated or cicatrized pylorus operation may be made directly upon the pylorus-pyloroplasty—according to the method of Heinecke-Mikulicz or of Finney. The operation of Heinecke-Mikulicz consists in simply incising and enlarging the ulcerated or cicatrized pylorus and has the disadvantage that the diseased part of the stomach is the portion where the incision is made, sutures inserted, etc. The placing of the sutures and proper apposition of the edges of the incision may also be difficult on account of the density of the ulcerated, cicatrized tissues. The operation of Finney consists in making a very capacious communication between the pyloric end of the stomach and the first part of the duodenum, and has given good results so far as it has been tried. The objection that in this operation the field corresponds to the diseased area is nullified by the fact that in most instances the ulcerated area may be excised at the same time that the new opening is established. There may be some difficulty in mobilizing the fixed, adherent duodenum, but Finney claims that even in those cases where the duodenum seems almost hopelessly fixed by adhesions, by patient efforts it can be sufficiently detached so as to permit of the junction being made between it and the stomach. This operation provides a large, commodious opening from the stomach into the first part of the duodenum—the most desirable portion of the small intestine for the purpose of a gastroenterostomy.

Gastrojejunostomy.—A new opening is established from the stomach into the intestine. The pylorus is "short-circuited." This operation fulfills all the indications for the treatment of gastric ulcer, in that it provides ample and prompt drainage of the stomach and at the same time diverts the current of gastric contents away from the diseased areas. This method of treatment surely relieves the symptoms and indirectly cures the ulcer. It relieves the distressing symptoms by placing the stomach in a condition to promptly empty itself, and thus the organ is able to enjoy sufficiently long intervals of physiological rest, free from peristalsis and contact with retained strongly acid gastric contents. In this way the healing process is favored.

As a result of gastrojejunostomy extensive indurated ulcers involving the pylorus and body of the stomach have been seen to disappear and patients with all the clinical symptoms of cancer of the stomach have been restored to the full enjoyment of complete health. Even if the ulcer does not actually involve the pylorus we still frequently have associated obstruction at the pyloric orifice due to reflex muscular spasm, and hence in these cases also the gastrojejunostomy will have its beneficial and curative effect. The prime object of the operation is simply to put the stomach in a position to promptly empty iself of its acrid, ulcer-producing contents. These contents are the determining factors that are responsible in the first place for the production of the ulcer and then, later, for its failure to heal. In properly selected cases the operation of gastrojejunostomy, *per se,* carries with it but little or no danger of a fatal issue. It would appear that this ought to be the operation of choice for all cases of simple ulcer, where operative interference is indicated, but especially is it to be preferred to the other radical measures, such as excision of the ulcerated area, pylorectomy, etc., in all those cases where the patient's condition is already reduced or adhesions to important organs, etc., render these latter operations more dangerous. There are a number of methods of performing the operation of gastrojejunostomy, and with most of these we are all familiar. A few moments, however, might well be devoted to the description of the technique of the method employed by Czerny.

Gastrojejunostomy, Czerny.—Gastrojejunostomy without the formation of a loop. The upper part of the jejunum is situated normally behind and close to the posterior wall of the stomach and in this operation this portion of the gut is the part that is anastomosed to the stomach. It is fixed to the posterior surface of the stomach, near its greater curvature with a row of continuous, non-penetrating silk sutures. These sutures secure the gut along a line transverse to its long axis and extend about half way around the circumference of the gut. After this line of suture has been introduced the needle is dropped temporarily until required later to complete the row of outside, non-penetrating sutures. An opening is made in the stomach and one in the attached gut, the incision in the gut being made transverse to the long axis of the intestine. The edges of the openings in the stomach and jejunum are stitched together with a continuous, penetrating catgut suture. The needle, still carrying the silk thread with which the first half of the outside non-penetrating suture was introduced, is then again taken in hand and the second superficial half of this line of suture inserted, thus completing the operation. The anastomosis may also be made very expeditiously with the Murphy button.

It is claimed for this method of gastrojejunostomy that the phenomena that make up the so-called "vicious circle," and which are responsible for a considerable number of the deaths following the operation, are entirely obviated.

Radical Operations for Ulcer.—Under this heading are included those operations that aim to eradicate the ulcerated area.

Infolding of Ulcerated Area.—This plan may be practiced when the location of the ulcer, etc., are favorable. The ulcerated area is disposed of by infolding it into the lumen of the stomach and it is retained thus with one or two rows of sutures. The infolded area by this procedure is thrown out of activity and gradually disappears by a process of atrophy. It would probably be advisable in these cases also to establish a gastrojejunostomy in addition to infolding the ulcerated area of the stomach wall.

Excision of Ulcerated Area.—This operation might be employed in certain exceptional cases where the ulcer is accessible, especially if it is limited to the anterior wall, and if the character of adhesions does not preclude the possibility of its successful performance. The defect that is left in the wall of the stomach after the ulcer has been excised is closed with a continuous penetrating catgut suture, which is reinforced and buried by a continuous, non-penetrating silk suture. If the ulcer occupies the posterior wall of the stomach it may be excised through an incision in the anterior wall. The opening that is left in the posterior wall of the stomach after the ulcer has been excised is closed with a continuous penetrating catgut suture, which is applied from within the stomach, through the opening in its anterior wall, and this line of suture then reinforced and buried by a non-penetrating silk suture, which is applied to the wall of the stomach from without, the surgeon working through an opening which is made for the purpose in the gastrocolic ligament or in the transverse mesocolon.

Pylorectomy.—If the pyloric portion of the stomach is the part involved in the ulcerative process, then pylorectomy is the preferable operation for immediate radical cure. The pyloric portion of the stomach may be resected according to any of the usual methods (Billroth, Kocher, Hartmann), the continuity of the gastrointestinal canal being restored afterwards by either a gastroduodenostomy, according to Kocher or Billroth, or a gastrojejunostomy, anterior or posterior.

For Accidents.—It may be necessary to operate for the purpose of controlling hemorrhage, or in the event of perforation.

For Hemorrhage.—Surgical measures for the control of hemorrhage from gastric ulcer should be undertaken just as soon as it becomes evident that the bleeding cannot be controlled by the usual non-operative measures, or if the hemorrhage is very profuse, showing that a large vessel has been eroded or if the hemorrhage is repeated after a short interval. Hemorrhage occurring in young anemic women is less likely to terminate fatally than in older women or in men.

The stomach should be exposed and opened and an effort made to locate the bleeding point. If a single individual vessel, the attempt should be made to clamp and ligate or to cauterize it or the ulcerated area may be excised. If unable to secure the bleeding point a gastrojejunostomy should be performed. If this operation is done the bleeding will usually cease spontaneously, and the gastrojejunostomy continues to work indirectly to effect a radical cure of the lesion itself.

For Perforation.—Perforation of an ulcer into the free peritoneal cavity is almost invariably fatal unless the opening in the stomach is quickly closed and the abdomen cleansed of escaped stomach contents. There may be more than one perforation.

The opening in the stomach is closed with suture, or if this cannot be done a piece of gut or omentum may be sutured against it, to shut off the cavity of the stomach from the peritoneal cavity. After the opening in the stomach has been closed the abdominal cavity should be cleansed, either with moist aseptic wipes or else by flushing with normal salt solution.

For Remote Sequelæ.—Of the remote sequelæ that call for operative interference, we have perigastric adhesions and subphrenic abscess.

Perigastric adhesion may remain after a gastric ulcer has healed and may be so annoying as to call for operative interference. The adhesions should be separated or divided, gastrolysis. When operating for gastric ulcer, adhesions, if present, should be disposed of at the same time. Robson relates a case of old healed ulcer, where adhesions had persisted afterward, and continuing to cause symptoms required to be divided. The bleeding surfaces left after separation or division of adhesions may be covered over with omentum in order to prevent reformation of the adhesions.

Subphrenic Abscess.—This condition may call for incision and drainage independently of the gastric ulcer, which was the primary cause of its existence.

ERYSIPELAS WITH AN EXCESSIVE PRODUCTION OF FIBRIN.

By ROLFE FLOYD, M.D.,

NEW YORK

In erysipelas the essential inflammatory changes are confined to the skin, and consist of (1) congestion of the blood vessels; (2) exudation of serum, of blood cells, especially leucocytes, and of fibrin, the latter usually in small amount; together with (3) an increase of small round cells. These changes are associated with the growth of streptococci, chiefly in the lymph channels. The lymph nodes corresponding to the inflamed region are apt to be also inflamed.

The anatomical type of the inflammation may be modified by (1) the degeneration of the epidermis with the formation of larger or smaller vesicles or blebs, which contain serum or a serofibrinous fluid that forms crusts on drying; (2) the death of certain areas of the derma; (3) the extension of the inflammation to the subcutaneous cellular tissue in which small or large collections of pus are then apt to appear.

It is the object of this paper to report a case which, although presenting all the above features except the enlarged lympathic nodes, exhibited, in addition, an exudate of fibrin, so excessive and so disposed, as to constitute a croupous inflammation, that is, an inflammation of the skin presenting the same essential characters as a croupous colitis or a croupous inflammation of the throat.

On May 15, 1904, the patient, a coachman, thirty-eight years old, noticed that the back of his right hand was red and swollen. The next day the swelling increased, and became very painful; he had chills and felt feverish. He came under observation on the third day, when the chills had stopped, and the hand was less painful than the day before. The man was only a little sick. There was a typical erysipelas of the whole dorsum of the right hand. The skin was bright red and shiny, the margins of the inflamed area were sharply defined. A wet aluminum acetate dressing was applied.

On the fourth day the conditions remained unchanged.

On the fifth day the whole forearm was edematous, but not red. No enlarged lymph nodes could be found.

On the sixth day the erysipelas was spreading up the edematous forearm.

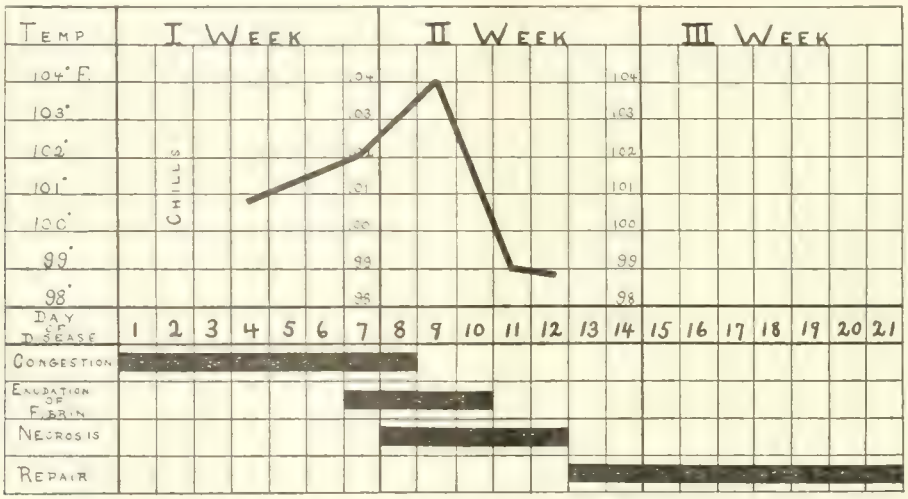
On the seventh day the man was sicker. The whole forearm was involved and vesicles began to appear on the dorsum of the hand.

On the eighth day these vesicles had changed into large confluent bullæ all over the dorsum of the hand and lower half of the forearm. On puncture a clear gelatinous fluid exuded. Removal of their epidermal covering revealed a layer of fibrin, practically continuous over the area occupied by the bullæ. This fibrinous false membrane varied in thickness from ⅜ in. (1 cm.), at the roots of the fingers, to ⅛ in. and less on the forearm. Where it was removed, as could be rather easily done, the exposed derma was roughened and reddish, except in the middle of the back of the hand and wrist, where it was blackish and necrotic. The advancing margin of the erysipelas had by this time (the eighth day), extended from the elbow half way to the axilla, along the inner side of the arm. A strap of adhesive plaster was put around the limb above the inflamed area with the result that the erysipelas never transgressed this barrier. Dr. Rundquist, who saw the case with me, and at whose suggestion the strap was put on, found no evidence of invasion of the subcutaneous cellular tissue at this time.

On the ninth day the man was at his sickest, being moderately delirious with high fever and looking thoroughly poisoned. The fibrin was still coming out on the derma and the necrotic area was a little larger and blacker.

On the tenth day the man was better, with no further delirium. The exudation of fibrin had almost stopped. The other local conditions were as on the day before.

On the eleventh day the man was still better. The erysipelas of the upper forearm and arm, which had never exhibited vesicles or other unusual features, except an associated phlebitis of the basilic vein, was beginning to fade. The derma of the dorsum of the hand and lower forearm, was afloat on pus which oozed through holes in the necrotic area. Incisions were made through the derma to let the pus out.



On the thirteenth day the erysipelas was practically over, though there was some tendency to form pus pockets under the overhanging edges of the large and irregular ulcer which was left on the back of the hand and wrist by the separation and removal of the necrotic area of derma. On the base of this ulcer could be seen the extensor tendons, not quite exposed.

On the fourteenth day the wound was fairly beginning to clean, and the tendons were protected by a thin layer of healthy granulations.

The ulcer proved most difficult to heal. For two months pus pockets kept appearing under its edges and the healed skin beyond its margins would break down in small areas to form additional points of ulceration. The skin edges advanced but feebly, the base never cleaned up nicely and there was always such a profuse purulent discharge as to make skin-grafting out of the question. No treatment, except keeping it clean, proved of real value.

Four months from the beginning of his illness the man went back to work, and the function of the arm and hand returned completely, except for a slight stiffness of the wrist joint.

There is still (February, 1905), an ulcer 2 in. by 1 in. on the back of his wrist, surrounded by skin of poor vitality.

The relative duration of the stage of congestion, the period of the exudation of the fibrin, and the period of necrosis, together with the temperature curve, are shown in the accompanying chart. The correspondence of the period of exudation of fibrin with the period of maximum temperature is interesting.

It is to be regretted that no attempt was made to determine what micro organisms were present.

AN UNUSUAL CASE OF BRADYCARDIA.

By JULIUS H COMROE, A.B., M.D.,
LECTURER ON THERAPEUTICS, TEMPLE COLLEGE, PHILADELPHIA.

Mrs. H. K. of Mahanoy City, Pa., aged 54, married, white. The family history was absolutely negative. Menstruation began at the age of 14, has always been regular and there has been no dysmenorrhea. She has had two miscarriages and six children, all of whom died in early childhood. Does not use alcohol and takes tea and coffee in moderation. Excepting measles and two attacks of mumps, she has never been confined to bed for illness.

The present condition dates back over a period of three years. At that time, following an injury to the right breast, the patient was greatly annoyed by a burning sensation and severe itching at the seat of traumatism. This never disappeared. Shortly afterward, she noticed a "fullness" in the right mamma, particularly confined to the upper outer quadrant. She consulted a physician, but no relief followed. This fullness soon developed into a distinct nodule, or "lump," which could be easily palpated. There was never any pain in this region. The tumor slowly but persistently increased in size and the same subjective symptoms continued to be present. It may be mentioned that the appearance of the tumor and the menopause were at approximately the same time.

The patient was referred to me for examination and treatment. I found her to be a well nourished white woman of good proportions, looking younger than the age implied. The pupils were moderately dilated, equal and presented normal reactions, conjunctival, nasal and buccal mucous membranes were of good color. Tongue clear, was protruded in the median line and was not tremulous. There was no thyroid enlargement and no superficial glandular enlargements. Pulses were equal, regular and of good quality. Rate 76 per minute. Thorax was of good proportions, expansion 2¼ inches. Pulmonary resonance and breath sounds were good. The heart was not enlarged, with sounds exceedingly clear, the muscular element being very good. Some accentuation of second pulmonic sound was noted. There were no murmurs or thrill.

The right breast was slightly larger than left, nipple not retracted and skin freely movable everywhere. The upper outer quadrant presented, on palpation, a distinct, hard mass, about the size of a hen's egg, and dipping toward the axilla. This was freely movable everywhere. There was slight pain on manipulation. No pectoral axillary or clavicular glandular enlargement. The liver extended from the fifth rib to the costal margin and was not tender. The spleen was not palpable. No tumors were present in the abdomen. The diagnosis was made of fibroadenoma, possibly undergoing scirrhous changes and complete removal was advised.

The anesthetic was given by Dr. Sidney Feldstein, with the patient in good condition and pulse of 90. A crescentic incision about four inches long was made and the tumor found to be about twice as large as a hen's egg and firmly enveloped in its capsule. Complete removal of the tumor down to the thoracic wall was carried out and a skin dissection of the flap made. I also cleaned out the axilla as far as possible. Silkworm gut through and through sutures and tube drainage were employed. The operation lasted one hour and five minutes. During the operation the pulse fluctuated between 80 and 90.

First day after operation the patient had little pain at seat of operation and voided urine (℥xxiv). Temperature 99.4, pulse 64.

Second Day.—The patient felt very well. Two grains of calomel were given with effect. The dressing was removed, and the wound edges found in healthy condition. There were no signs of infection and the tube was removed. Temperature 99.2, pulse 52.

Third Day.—The patient had had a few heat flashes during the night, and complained of severe itching in the wound. Temperature 100, pulse 46.

Fourth Day.—The wound was redressed and found to be healing by first intention and without tenderness. The patient was very hungry. Temperature 98.6, pulse 40.

The sutures were removed on the seventh day, leaving a clear, healthy wound. During the first week after the operation the pulse fluctuated between 40 and 64, and on the tenth day it was only 35 per minute. In every other respect the patient felt very well. The urine was negative.

1617 North Tenth Street.

ACUTE POSTERIOR PERIURETHRAL ABSCESS.

By FERDINAND C. WALSH,
WASHINGTON, D. C.
INSTRUCTOR IN GENITO-URINARY SURGERY MEDICAL DEPARTMENT OF GEORGETOWN UNIVERSITY.

Among the gravest complications met with in the treatment of gonorrhea is that of pus formation in the tissues surrounding the posterior urethra, due to infection of the deep urethral follicles. It is in these cases, in which expectant treatment alone has been carried out, that we so often meet with resulting infection of the seminal vesicles, prostatitis, chronic cystitis, and ascending infection of the genital tract, possibly leading to pus formation in the kidney, the most deplorable of all gonorrheal sequelæ.

On account of the close relationship of the structures surrounding the deep urethra, it is, except in sharply defined cases, practically impossible to define with exactness the pus location—that is to say, whether the abscess is situated anteriorly, posteriorly or laterally to the urethral canal; but a careful examination, both by digital exploration through the rectum and by external palpation of the perineum, will demonstrate approximately the seat of the trouble. In these cases instrumentation through the urethra by means of the cystoscope or urethroscope is worse than useless.

Abscess of the urethra of gonorrheal origin presents certain constant symptoms which are positively diagnostic. The patient gives a history of gonorrhea, and complains of pain, generally of an intense character, located deep in the perineum. Cystitis is almost invariably present, urination taking place every few minutes and followed by pain, due to the increase of tension caused by contraction of the muscular structure of the urethra. The bowels are constipated and defecation is painful. The recumbent position is the most comfortable. The urethral discharge is generally slight, but always contains

gonococci. The temperature is of the usual septic character. There is an extreme condition of restlessness and anxiety, and rectal and perineal palpation always elicits localized pain.

These symptoms call for immediate action on the part of the surgeon if he would avoid dangerous sequelæ, for palliative measures, while relieving pain temporarily, only allow the destructive process to continue, the perineum becoming more deeply involved.

The patient being prepared as for an ordinary external urethrotomy, an incision is made in the perineal raphe down to the urethra, evacuating in this way any pus met with en route. The urethra is then freely opened and an exploration is made with the index finger which readily detects the presence of pus cavities and easily curettes them. After exploring as far back as the bladder, and evacuating all cavities, this viscus should be thoroughly flushed with hot boric acid solution, and a full-sized fenestrated rubber catheter inserted and secured in position through the urethral opening.

Subsequent treatment should consist in washing the bladder twice daily (with the same solution) through the catheter, which should first be removed, cleansed, and then reinserted. The penile urethra should be irrigated with an antiseptic solution whose strength should depend on the condition of the urethra. The bowels should be kept freely open, abundant water given, a urinary antiseptic employed, and a light diet instituted. On the third day, in favorable cases, when pus formation has not been extensive, the drainage-tube may be removed from the urethral wound, and a catheter inserted through the penis and held in to promote continuous drainage, allowing the posterior urethra to regain its continuity. Through this catheter, which likewise should be daily withdrawn and washed, the bladder should be irrigated, some of the fluid returning between it and the urethral walls, when distension of the bladder occurs. By the sixth day the catheter may be removed permanently, and the urethral incision will be found practically closed.

In cases in which extensive suppuration has taken place, the surgeon should be guided by circumstances in determining the time when drainage through the urethral wound may be discontinued. Sounds should not be employed until the sixth day, after which they may be passed every third day until the surgeon is satisfied that the urethral lumen is restored.

I have recently met with several cases in which the foregoing treatment has been instituted, and all of the patients have been able to leave the hospital within ten days, returning to the office for subsequent treatment.

The Albany

Eclampsia.—Allen, who believes that this condition is due to a maternal toxin, probably having its origin in the liver, summarizes the treatment as follows: (1) Treat premonitory symptoms until in spite of the treatment they get worse, then empty the uterus, as in some cases this is the only method of stopping the progress of the disease. (2) Deliver as quickly as possible, consistent with cleanliness and preservation of soft parts; bleed, removing from 300-700 c.c., as the case may indicate; infuse, giving from 500-1000 c.c. of salt solution, depending upon the amount of blood withdrawn and character of pulse; this may be repeated later; morphia gr. ¼, hypodermatically to relax the muscular system; croton oil gtt. 1—gtts. 11 in olive oil 5i 3ii, followed by magnes. sulphate 3ss in saturated solution until effectual as purgative. (3) Milk and water diet. (4) Other conditions treated symptomatically.—*American Journal of Obstetrics.*

REPORT OF AN INTERESTING CASE.

By E. B. VAN ARSDEL, M.D.,

Alamogordo, N. Mex.

On Sunday, December 18, 1904, at 1 o'clock P. M., I was called to a labor case in a Mexican, aged twenty years, a primipara, woman very small, weight about eighty-five pounds. The sanitary surroundings were of the poorest. A very close hut, bed linen scanty, badly soiled, and much the worse for wear. She had been in labor since 4 A. M., and inspection of abdomen showed a deformity which led me to suspect a transverse presentation. Upon palpation my suspicions were strengthened and a digital examination confirmed the diagnosis—a left cephaloiliac, or dorso-posterior position. The vaginal orifice was patent, moist, and free from obstruction; the pelvis was normal, the os thoroughly dilated, membranes unruptured; the left hand was presenting rather high. This examination was made with the left hand. After I had made external manipulation for a few minutes only, without any perceptible result, my associate was sent for and arrived one-half hour later. Before administering chloroform, he made an examination with the right hand, and found both feet presenting. Upon re-examination, I found both hands and feet presenting, which is extremely rare. The head in left cornu, and breech in right. Chloroform was administered, the membranes were ruptured, and podalic version by combined external and internal manipulation was done; the feet were brought down, and in twenty minutes a live male child was delivered without injury.

After waiting the usual time, Credé's method failed to deliver the placenta. It had to be dissected away with finger-tip, and it came away readily, though the membranes were very adherent in the right coru of the uterus, which was afterwards found to be bicornate of the most marked kind. The mother made an uneventful recovery.

Another feature of interest in this case is that when attention was directed to the child a penile hypospadias was discovered with no visible meatus, and none could be detected until next morning, when the mother complained of the child's inability to void urine. The child was placed in a bowl of warm water, a narrow, triangular, pin-point opening was noticed at the penoscrotal fold, which emitted the urine in a pin-point stream, very forcibly. The penis was undeveloped, clitoris-like, and curved downward; the prepuce was deformed, being well developed on top, and entirely absent on the under surface and toward the frenum.

A hard ridge alone marked the course of the normal urethra from the abnormal meatus to the apex of the glans. The scrotum was distinctly divided into two halves by a furrow (apparently cicatricial) and hung not unlike the labia of a female child. The scrotum, well developed, was simply a wrinkled mass, the testicles, of course, having not yet descended.

In all, we considered it a very interesting case. Transverse presentation, one in about two hundred and fifty; both hands and feet presenting, extremely rare; obstinate adherence of membranes, marked bicornate uterus, and a penile hypospadias, Chaussier found, among 23,293 new-born at the Maternité of Paris, one hundred and thirty-two malformations, two of which were hypospadias. Some claim this an entirely too low proportion, and the statistics vary much; but of its infrequency there can be no doubt.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, April 22, 1905.

TYPHOID FEVER IN CAMPS.

THE "Report on the Origin and Spread of Typhoid Fever in the United States Military Camps during the Spanish War of 1898," has been issued from the Government Printing Office.* It was prepared in accordance with act of Congress, under the direction of the Surgeon-General, and is the result of the joint labors of Dr. Victor C. Vaughan, Dr. Walter Reed, and Dr. Edward O. Shakespeare, who constituted the board of army surgeons which investigated the matter in 1898 and subsequently. In the meantime Drs. Reed and Shakespeare having died, the whole labor of collecting and arranging the data and preparing the publication of this monument of professional skill and learning, fell upon the shoulders of Dr. Vaughan. The detailed data, text, and the conclusions of the board are in the first volume—a quarto of about 700 pages—while the 96 maps and charts are in the second volume—a folio. Together they furnish material for earnest thought upon the numerous problems of the prevention of typhoid fever, which are constantly presented to both civil and military sanitarians. The medical profession and, indeed, the whole nation, owes a debt of gratitude to the authors and particularly to Dr. Vaughan, for their labors.

Still, the publication at this time, or rather republication, for the conclusions were announced in 1899, causes a feeling of almost sadness, since there is scarcely anything elicited which was not previously known by the profession. It is doubly sad that the dark history now revealed in all its ghastly details might have been prevented, and one naturally wonders whether it will happen again. The faults appear to be largely those of organization and to a great extent inseparable from military systems. Nevertheless it can be prevented or it would be a confession of incompetency in the Army administration to admit that it is powerless to control its soldiers and their health in camp. The nation is patiently waiting to learn of the steps being taken for the future, trusting to the hard common sense of our representatives when they are brought face to face with a serious problem. So far they have done nothing, and the only thing for physicians to do is to convince them that it is a serious problem. In the meantime if we will take to heart the lesson that typhoid infection exists in every part of this country at all times, and is sure to appear in 98 per cent. of all regiments, Vaughan, Reed, and Shakespeare will have conferred a blessing equal in importance to the discovery of the methods of avoiding malaria and yellow fever.

The lesson which seems to have been learned by the Government, if not by all of its officers, at least by those who think, is that stupid interference with sanitation is a serious matter warranting dismissal of the offending officials, and this course of action by the President in the Panama case has received the sanction of the press. The time is now ripe for the passage of a law that any officer who obstructs sanitation or ignores the advice of his sanitary officers, shall be dismissed. The army must purge itself of dangerous men to avoid a repetition of the awful typhoid record of the Spanish War, and the necessity of this new law is self-evident. If not demanded now by thinking people, it surely will be in the course of time.

*Report on the Origin and Spread of Typhoid Fever in U. S. Military Camps during the Spanish War of 1898, by Walter Reed, Major and Surgeon, U. S. Army; Victor C. Vaughan, Major and Division Surgeon, U. S. Volunteers, and Edward O. Shakespeare, Major and Brigade Surgeon, U. S. Volunteers. Prepared in accordance with act of Congress under direction of Surgeon-General Robert M. O'Reilly, United States Army. Vol. I., Text; Vol. II., Maps and Charts. Washington: Government Printing Office, 1904.

HIGH ALTITUDES FOR CONSUMPTIVES.

THE question as to where to send sufferers from pulmonary tuberculosis is one on which there is no unanimity of opinion among the members of the medical profession. There are many physicians who now assert that the importance of climate in the treatment of consumption has been greatly overestimated, and that much benefit may be derived from an outdoor carefully regulated existence even in a moist climate. On the whole, however, the belief is general that, other things being equal, a dry climate with plenty of sun affords the most favorable conditions for the consumptive.

In the *Journal of the Association of Military Surgeons* for February, 1905, is an article by Dr. Paul M. Carrington of the United States Public Health and Marine Hospital Service, treating of altitude with special reference to the treatment of consumption. The writer, like many others, is convinced that sending consumptives to high altitudes indiscriminately and without carefully considering the individual indication for such treatment has shortened the lives of many, and doubtless caused the early death of some, whose disease under more judicious management, might have become arrested or cured.

It has been observed clinically in the case of consumptives in the Fort Stanton Sanatorium, which is situated at an altitude of 6,150 feet, that there is an immediate and rapid increase in the hemoglobin following their arrival. This is due to the thinness of the inspired air, and to an effort of nature to readjust the individual to his new environment and provide for a greater assimilation of oxygen.

Dr. Carrington treats at length of thoracic expansion, defining it clearly, and showing under what circumstances expansion and vital capacity are affected. As to why expansion should govern in determining the proper altitude for a consumptive patient, the writer explains in the following words: "It stands to reason that Case I, with two inches of expansion representing one hundred and twenty cubic inches of vital capacity, and barely able, at sea-level, to appropriate sufficient oxygen to maintain an ordinary metabolism should not do so well at an altitude of over six thousand feet as Case II, with

an expansion of four inches, representing a vital capacity of three hundred and forty cubic inches, and consequent appropriation of twice the volume of oxygen. The blood of Case I. being insufficiently oxygenated fails to perform its functions completely and the patient suffers from dyspnea and perhaps from cyanosis with increased cough and expectoration and extension of tuberculous areas, nature striving, without avail, to increase the hemoglobin with sufficient rapidity to supply the essential oxygen And on the other hand, Case II, with a moderate increase of hemogloblin, is amply supplied with oxygen, all the symptoms abate, and at the first examination, three months after admission, there is usually found a marked diminution of lung-tissue involved. In the two cases it is supposed that the percentage of lung-tissue compromised is the same."

Dr. Carrington concludes by reiterating his views as to the inadvisability of indiscriminately sending consumptives to the high altitudes of the arid Southwest. He says that he has long held the opinion that in cases otherwise suitable, the patients may under preliminary home treatment have their vital capacity so increased as to render them fit subjects for residence in high altitudes, or they may be sent with profit to the lower altitudes of the same general region, where any desired altitude from 14,000 feet above sea level to an actual depression below sea level can be had.

Epidemic of Diphtheria in the Willard State Hospital.

For several years diphtheria has prevailed at the above institution. A report of the epidemic by Dr. William L. Russell, medical inspector of institutions for the insane, State of New York, and Dr. Thomas W. Salmon, Assistant Surgeon U. S. Public Health and Marine Hospital Service, has been issued recently. The careful investigations made with regard to the disease from the time of its first outbreak in June, 1899, to January 1, 1903, cannot but be of great scientific interest and value. The mortality has been very low. The chief means of treatment has been by antitoxin. Hydrogen dioxide was occasionally used with success for the removal of necrotic membrane. The spread of the infection from the first two cases in 1899, the writers say, affords an interesting illustration of the natural history of an epidemic of contagious disease and of the limits of our ability to trace the paths of infection as they branch and rebranch with the widening of the infected area. It also demonstrates the importance of immediate thorough isolation of the first cases and their environment from the rest of an institution or other community. Besides contact with the sick, the direct means of spread of diphtheria at Willard, so far as can be demonstrated, were: (1) Contact with recovered cases; (2) contact with unsuspected clinical cases, especially those in which there was no pseudomembrane, and mild nasal cases; (3) contact with well persons infected with diphtheria bacilli, and (4) in six instances, contact with infected articles or rooms. The importance of the early employment of antitoxin was amply demonstrated, while the epidemic has afforded additional proof that the bacteriological diagnosis of diphtheria is one of the most reliable applications of a laboratory test to a clinical condition that we have. In the laryngeal cases, however, where the importance to the patient of an early diagnosis is greatest, the bacteriological test often fails. Since the close of the period covered by the above report, December 31, 1902, to September 30, 1904, the number of cases of diphtheria at Willard has been thirty-two. The history of the epidemic for the past three years indicates that, with the exception of sporadic cases, the disease has been practically confined to the main hospital building and the two infirmaries. Improved sanitary conditions in these buildings and strenuous efforts to limit the spread of infection should new cases appear will probably be followed by complete suppression of the epidemic in the near future.

Problem of Immigration.

Dr. Allan McLaughlin, in the *Popular Science Monthly* for April, again attacks the problem of immigration. Among other arguments he brings forward, is that foreign skilled labor is no longer needed in the United States; not only is such labor not required but its exponents are undesirable immigrants. Foreign skilled laborers are town dwellers and of poor physique and their advent tends to intensify further the present unsanitary conditions of tenement districts in large American cities. Dr. McLaughlin suggests three remedies for the exclusion of undesirable immigrants: (1) The imposition of a head tax; (2) an illiteracy test; (3) a definite standard of physique. The imposition of a head tax is a last resort, and need not as yet be seriously considered. An illiteracy test would cut both ways, for while it would bar many undesirables, it would also shut out many persons greatly needed in this country. Strong, lusty laborers must be had to do the rough manual labor here, for the supply of this class in the United States is not nearly equal to the demand. The majority of imported laborers are, in the nature of things, more or less illiterate. Dr. McLaughlin thinks that the standard of physique should be definitely prescribed by law and every male immigrant should be required to pass a physical test. Each family should be required to possess at least one male, supposedly the bread winner, who could come up to certain prescribed requirements. The great difficulty met with in the endeavor to solve the immigration problem successfully is the tendency of immigrants, and especially those of Italian nationality, to flock to the great cities. If they would spread over an extended area their presence would be a boon rather than it frequently is now a bane to the country. Agricultural districts would welcome the strong, hard-working foreigner and a rural life would be better in every respect for all concerned. Under existing conditions the poorer sections of the large centers of population are rendered more and more unhealthy by reason of the overcrowding engendered by the too gregarious habits of ignorant foreigners.

Sanitary Rules for White Men in the Tropics.

The greatest cause of sickness among white men in the tropics is ignorance of sanitary laws. It is generally agreed that if the Caucasian, who makes a tropical country his home, will only live in a manner best befitting the climate in the majority of cases he will retain his health, at least for a considerable period. Major P. G. Ivers of Royal Army Medical Corps is contributing to the *Journal* of that corps some sanitary notes for recruits. In the issue for February, 1905, he recommends certain precautions to be taken by newcomers in tropical regions. He points out that the greatest care should be taken to ensure a pure water supply, and repeats the common statement that there is no safer method known

for purifying water than that of simple boiling. The importance of wearing a flannel belt is also insisted upon, as by this means an equal temperature or heat of the body is kept up and the danger of sudden chills avoided. The writer lays special stress upon the necessity for temperance, and states that temperance both in conduct and at the table is a *sine qua non*, if the individual is desirous of preserving his health in the tropics. We fear the writer is more theoretical than practical in his recommendations. No one will find fault with his not particularly novel suggestion to boil the water, nor with his praise of temperance—which need not necessarily mean teetotalism. But his insistence upon the hot, sticky, and uncomfortable flannel belly band sounds like a voice from the past. A wet compress worn constantly over the abdomen and loins is not to be recommended as a means of preserving from sudden chill.

A Law to Check Adulteration.

An act has been introduced into the New York State Assembly, by Mr. Fish, to amend section one hundred and sixty-five of the agricultural law. This section deals with the question of food adulteration, and of the offering for sale of food unfit for human consumption. The new matter in the act refers to slaughtered game, animal or poultry, and provides that the carcasses of such slaughtered game, animal or poultry, shall be divested of the lung tissues, entire digestive and intestinal tracts, gall receptacle, craw, and gizzard lining within forty-eight hours after slaughter. Any law which aims at preserving food from adulteration is in these days worthy of the highest commendation, and should be supported by public opinion. The amendment to the law to which attention has been called seems to be a reasonable and needful one and is another step in the direction of ensuring to the people good and pure food.

News of the Week.

The National Anti-Tuberculosis Meeting.—The plans for the annual meeting of the National Association for the Study and Prevention of Tuberculosis to be held in Washington, May 18 and 19, under the presidency of Dr. Edward L. Trudeau, are now rapidly approaching completion. At the general meeting of the association to be held on the morning of the 18th, addresses will be made by the president and by the two vice-presidents, Drs. William Osler of Baltimore, and Hermann M. Biggs of New York. At a general meeting to be held on the evening of the 18th, an address will be made by Mr. Talcott Williams, of Philadelphia, to be followed by the business meeting of the association. The afternoon of the 18th, and the morning and afternoon of the 19th, will be given up to meetings of the Sociological, Clinical and Climatological, and Pathological and Bacteriological sections. Invitations have been sent to the various anti-tuberculosis organizations in the United States to be represented by delegates at this meeting and a large attendance is expected.

Association of American Medical Colleges.—The fifteenth annual meeting was held in Chicago, April 10, 1905. The Association has adopted a new Constitution and By-Laws, so that now the annual dues are raised to $25.00. The minimum entrance requirement was made a diploma from an accredited high school, normal school, or academy requiring for admission evidence of the completion of an eight-year course in primary and intermediate grades, and for graduation not less than four years of study, embracing not less than two years (4 points), of foreign languages, of which one must be Latin, two years (4 points), of mathematics; two years (4 points), of English; one year (2 points), of history; two years (4 points), of laboratory science, and six years (12 points), of further credit in language, literature, history, or science. The applicant is required to take an examination in prescribed subjects, equaling a credit of 30 points, or he must present certificates from reputable instructors recognized by the Superintendent of Public Instruction in the city or State in which the college is located, or by any State board of medical examiners duly authorized by law, which might be accepted in lieu of any part of this examination. Provision is made for a four-year course of study in four calendar years, each annual course to have been not less than 30 teaching weeks, including examinations, duration, and at least ten months intervening between the beginning of any course, and the beginning of the preceding course. Credit may be given to the holder of a Bachelor's degree for any work in the medical branches which he has successfully completed in his college course, only so far as it is the full equivalent of corresponding work in the medical curriculum. The holder of such degree may also be given time credits of not exceeding more than one year; provided he has had at least forty hours in physics, 144 hours in chemistry, 24 hours in osteology, 292 hours in human or comparative anatomy, 124 hours in histology, 85 hours in embryology, 145 hours in physiology, and 46 hours in materia medica, provided that the applicant satisfies the professors of the Chairs in the medical school as to his proficiency in these first year medical studies. Every student is obliged to attend eighty per cent. of the exercises in every annual course of study for which he seeks credit, and no credit shall be given unless he attains a grade of at least 70 per cent. or its equivalent in any other marking system. No student can be graduated unless he attains a passing grade in each and all subjects of the required curriculum. Dr. Samuel C. James, of Kansas City, Mo., was elected *President;* Dr. Fred C. Zapffe, of Chicago, *Secretary-Treasurer.* The next meeting will be held in Pittsburg, in 1906.

Pennsylvania Society for the Prevention of Tuberculosis.—At the thirteenth annual meeting, held April 12, the retiring President, Dr. Howard S. Anders, criticised severely the action of Governor Pennypacker in vetoing the bill passed by the Legislature for the establishment of tuberculosis camps in the Forestry Reserve of the State. He further pointed out the danger of alcoholism as an etiological factor in lowering the resistance to tubercle-bacilli, and he recommended effectual legislation against the marriage of tuberculous individuals. He made a plea that greater consideration be given to the prevention of tuberculosis among children. He dwelt on the dangers from the use of common drinking cups in public places, schools, etc. He suggested that children in the schools should be taught, in the course of hygiene, the fundamental principles concerning tuberculosis, such as proper modes of living especially antagonistic to the development of the disease, cleanliness in the home, and the like. The following officers were elected for the ensuing year: *President* Dr. Joseph Walsh; *Vice-Presidents,* Dr. M. P. Ravenel, Dr. Benjamin Lee, Mr. Talcott Williams, Dr. A. B. Craig, Dr. Howard S. Anders, Mr. Samuel Castner, Dr. Samuel G. Dixon, Dr. L. F. Fick, Dr. Samuel Scoville, Jr., Dr. Seneca Egbert; *Secretary,* Dr. Ward Brinton.

War Against the Peripatetic Quack.—The physicians of Lebanon, Ohio, are pretty thoroughly organized for business and protection. One of their

latest contests was against the patent medicine fakir. One of that sort of street vendor entered the town not long ago and was as promptly arrested as the evidence against him could be secured. He claimed to be from Virginia, to have studied medicine in Louisville, Ky. Of course, the local doctors were accused of jealousy. In a newspaper paragraph written by himself the "doctor" claimed that he was persecuted and was perfectly innocent of violating the law, but as his business affairs needed his attention he said he would plead guilty and leave the town. The minimum fine was assessed and the man seemed to be glad to get away.

San Diego County, Cal., Medical Society.—The annual election of officers of this society on April 7, resulted in the choice of Dr. James M. French, President, and Dr. Willard N. Smart, Vice-President. Dr. Thomas L. Magee was reelected to serve his fourteenth consecutive year as Secretary and Treasurer. After the election, the society adjourned to the Hotel Brewster and enjoyed an elaborate dinner provided by the retiring President, Dr. P. J. Parker. This was followed by a valedictory address on professional unity, that awakened a most enjoyable discussion and did much to strengthen the friendly feeling advocated in the address.

New Hospital Island to Be Built.—The contract for the construction of a new island to be part of the Ellis Island immigrant station in New York Bay, has been awarded to a building company, which is to forfeit $25 for each day the work remains uncompleted after the expiration of 230 working days. On the new island is to be erected a hospital for minor contagious diseases. The contract price for the work is $119,000.

New York County Medical Association.—At the meeting of this association, held April 17, the following officers were elected: *President,* Dr. Francis J. Quinlan; *Vice-Presidents,* Drs. John A. Bodine and H. H. Seabrook; *Recording Secretary,* Dr. W. R. Stone; *Corresponding Secretary,* Dr. C. G. Childs; *Treasurer,* Dr. Charles E. Denison; *Member of Executive Committee,* Dr. H. A. Dodin; *Member of Nominating Committee,* Dr. Wisner R. Townsend.

Formalin War.—According to the weekly bulletin of the Chicago Health Bureau, the war waged against formalin in milk during the last five years has beeen successful to a gratifying degree. In the samples examined in 1904 there were 93.6 per cent fewer cases of formalin adulteration than were found in 1900. The report also says: "In 1900, the under-five-years-of-age population of Chicago by the United States census was 190,355, and the total deaths were 8,283, or 43.5 in every 1,000 of the under-five population. In the succeeding four years the proportions have been 38.9 in 1901; 40.9 in 1902; 41.7 in 1903, and 34.7 in 1904, a reduction of 1/5 (20.1 per cent.), in 1904, from the proportion in 1900."

An International Medical Association Against War.—It is stated in *The Lancet* that more than two hundred medical men met on March 21, at the house of Dr. Rivière, in Paris, the object being to establish an association of medical men for the purpose of doing all in their power to abolish war. It was decided to found an International Medical Association against War and it was proposed to hold a congress on the subject in two years' time. Those present were constituted the committee of the movement and officers were elected as follows: *President,* Dr. Rivière; *Vice-Presidents,* Drs. Philippeau, Suarez de Mendoza, and Th. Mende Ernst; *General Secretary,* Dr. Mazery; *Secretaries,* Drs. Pokinotoff, Antonelli, Cree, de Torres Mendiola, de Castro Soffia, and Cogrel; *Treasurer,* Dr. Marechal; *Delegated Secretaries,* Drs. Mazery, Cree, and Cogrel. Dr. Rivière, who opened the proceedings in an able discourse, reminded his hearers of the horrors of war; he pointed out how the North Sea incident showed very well what arbitration could do and argued that medical men who were so intimately acquainted with human misery, both physical and moral, were by that very fact the most fitted of the community to collaborate in the great work of substituting arbitration for war.

Physician Sued.—Because he failed to change his clothing when he visited a patient, a physician of Millstadt, Ill., has been sued for $2,500 damages. The plaintiff claimed that the defendant while treating the former's wife for pneumonia, was also treating several persons afflicted with smallpox, and that he went directly to the bedside of the patient with pneumonia, after attending to the smallpox cases without changing his clothing or taking other precautions to prevent infection. As a result of this carelessness it is claimed that the plaintiff's wife and his five children contracted the smallpox and were ill for several weeks.

Sanitary Condition of the Joliet (Illinois) Penitentiary.—A report on the sanitary condition of this istitution was recently presented by the Secretary of the State Board of Health, Dr. Jas. A. Egan, at a quarterly meeting of that body. The report pointed out the absolute necessity for increased facilities if the health of the 1,400 inmates is to be maintained unimpaired. According to the report, there is inadequate air space and lack of light in the present cell arrangement. No great increase in the death rate, however, has been demonstrated. A supplementary report on the air condition in the present cell houses is forthcoming by Prof. John H. Long, chemist; and Dr. Robert Zeit, bacteriologist.

The St. Louis College of Physicians and Surgeons held commencement exercises on April 14 and fifty-four graduates received diplomas. The faculty address was delivered by Prof. Wm. F. Francis, and the class valedictory by Marvin C. Prentz.

Wistar Institute Committee.—The board of ten anatomists appointed as advisors to the Wistar Institute of Anatomy of the University of Pennsylvania, has selected a committee of five to cooperate with the committee on cerebral study of the international academies. The object of the movement is to appoint representatives at points throughout the world for the purpose of collecting and preserving material for the study of the anatomy of the brain and of comparative anatomy and embryology in general. A general line of research has been laid down of which the ultimate object is the collection and study of the brains of men of distinguished character and ability.

Coroner's Bill Passes.—The bill introduced by Senator Elsberg to abolish the office of coroner in New York City and to substitute therefor medical examiners, was passed by the Senate after little opposition. If the bill is enacted the work of the coroner's office will be divided between the Police and Health Departments.

Medical Association of the District of Columbia.—The following officers for the ensuing year were elected at the recent semiannual meeting: *President,* Clifton Mayfield, M.D.; *Vice-Presidents,* D. Olin Leech, M.D., and G. Brown Miller, M.D.; *Secretary,* D. W. Prentiss, M.D.; *Treasurer,* Frank Leech, M.D.; *Counselors*: Standing Committee, G. Wythe Cook, M.D.; George N. Acker, M. D.; H. T. A. Lemon, M.D.; John S. McLain, M.D.; T. N McLaughlin, M.D.; E. L. Morgan, M.D.; James Dudley Morgan, M.D.; George C. Ober, M.D.;

William M. Spriggs, M.D.; *Censors,* L. K. Beaty, M.D.; Sothoran Key, M.D.; Louis Mackall, Jr., M.D.; *Delegate to the American Medical Association,* George M. Kober, M.D.

Metallic Ferments in Meningitis.—It is reported from Paris that Dr. Albert Robin, who, a short time ago described good results in the treatment of pneumonia by the intravenous injection of metallic silver and manganese in the colloidal state, to which preparations he has given the name of metallic ferments, has been treating meningitis by the same method in the Hopital Beaujon. The injections are said to be followed by a decrease in the temperature and improvement in the general condition.

Abbeville County, S. C., Medical Society.—This society has been organized with the following officers: *President,* Dr. J. W. Wideman; *Secretary,* and *Treasurer,* Dr. C. C. Gambrell; *Delegate to the State Association,* Dr. Jesse R. Bell.

New London County, Conn., Medical Society.—At the last meeting of this society, held at Norwich, the election of officers resulted as follows: *President,* Dr. J. G. Stanton, New London; *Vice-President,* Dr. C. E. Brayton, Stonington; *Clerk,* Dr. M. E. Fox, Montville.

Seizure of Patent Medicine in Maine.—The Prohibitionists of Maine are passing through one of their periodical endeavors to reform both the spirit and the letter of the liquor law in that State. They recently made a raid on the grocery store of a firm headed by the Governor and seized a large quantity of a popular and much advertised patent medicine, the claim being made that it contained an illegal amount of alcohol. A clean sweep will now be made of this and other proprietary medicines, alcoholically charged, throughout the drug and grocery stores of the State.

Deaths by Illuminating Gas.—The Gas Investigating Committee recently called upon the Coroner's office for statistics of gas poisoning in this city during the past three years. The compilation shows that the number of deaths, both accidental and suicidal, is increasing. The records show that in 1902 there were sixty-three accidental and sixty-eight suicidal deaths; in 1903, 123 accidental, and 93 suicidal, and in 1904 the figures were 130 and 133 respectively.

Cocaine Habituation Among Negroes.—In his charge to the March Grand Jury at Rolling Fork, Miss., Judge Oliver Catchings called special attention to the allegation that druggists all over the Mississippi delta were selling cocaine promiscuously to negroes. The evils attendant upon the use of the drug, according to Judge Catchings, cover the whole catalogue of crime, and he insisted that the Grand Jury should show no mercy in dealing with druggists who are found to have violated the law.

Salicylic Acid in Baked Beans.—Analytical tests made by the chemists of the Boston Board of Health and of the State Board have revealed the presence of salicylic acid in certain canned baked beans, sulphuric acid in hamburger steak, and boric acid in butter offered in the public markets of Boston.

"The American Journal of Surgery" is the title which was assumed with the April number of the *American Journal of Surgery and Gynecology.* The transformed and renamed journal is edited by Dr. Walter M. Brickner of this city and published by Dr. Joseph MacDonald, Jr., formerly manager of the *International Journal of Surgery.*

The California State Board of Health, at the annual election, held in Sacramento, April 1, reelected Dr. Martin Regensburger president, and Dr. N. K. Foster secretary, Dr. W. A. Briggs being chosen for vice-president. Dr. Foster was elected also delegate to the annual meeting of the State and Provincial Health Boards to meet at Washington, D. C., in May.

The Medical and Chirurgical Faculty of Maryland.—The one hundred and seventh annual meeting of this society will be held in the convention hall of the Hotel Stafford, Baltimore, on April 25-27, 1905, under the presidency of Dr. Edward N. Brush. The secretary is Dr. John Ruhräh.

The Hickman County, Tenn., Medical Society.—At the recent annual meeting of this society, the following officers were elected. *President,* Dr. A. Norris, of Centerville; *Vice-President,* Dr. J. S. Burley of Pinewood; *Secretary and Treasurer,* Dr. C. C. Stephenson of Centerville.

Dartmouth Medical School.—Plans have been made to reorganize the medical school of this college which dates from 1798, when Dr. Nathan Smith was made professor of medicine. The first step will be the erection of a building of large and handsome proportions facing the south, adjoining the present one. The proposed cost of the new building is $30,000, a large proportion of which has already been raised among the alumni.

Obituary Notes.—Dr. G. W. Phillips died at his home in La Junta, Colo., on March 23, at the age of eighty-three years. He was born in Berkshire County, Mass., and was graduated from the Indiana Medical College, La Porte, Ind., in 1846. In 1850 he went to California, but later went to Dixon, Ill. He served during the Civil War as surgeon of an Illinois regiment. In 1877 he removed to Colorado, where he continued to reside until his death.

Dr. William B. Small died at his home in Lewiston, Me., on April 13, at the age of forty-one years. He was a graduate of the Bellevue Hospital Medical School in 1888.

Dr. Milton Jay of Chicago, died March 31. He was dean and professor of surgery at the Bennett Medical College, and for many years was surgeon-in-chief of the Chicago and East Indiana Railway.

Dr. John W. Hamilton of Lampasas, Texas, died March 30, at the age of forty-five years. He was a graduate of the Medical Department of the Tulam University in the class of 1887.

Dr. Samuel D. Drewry died at his home in Centralia, Va., on April 2, at the age of seventy-three years. He was a graduate of the Medical College of Virginia in the class of 1854.

Dr. Albert K. Hadel of Baltimore died April 4, of pneumonia. He was a graduate of the University of Maryland School of Medicine in the class of 1889.

Dr. Herbert W. Cardwell of Portland, Ore., died April 3, of typhoid fever, at the age of forty-four years. He was a graduate of the Medical Department of Willamette University in the class of 1887 and of the College of Physicians and Surgeons, New York, the following year. After graduation he served on the house staff of the Methodist Episcopal Hospital, Brooklyn. During the Spanish War he was surgeon to the Second Oregon Volunteers and served three years in the Philippines.

Dr. John W. H. Baker died at his home in Davenport, Iowa, on April 7, at the age of eighty-four years. He was a graduate of the Dartmouth Medical School in 1843. He was an ex-president of the Iowa State Medical Society.

Dr. Samuel N. Bemis died at his home near Brattleboro, Vt., on April 8, of pneumonia, at the age of eighty-two years. He was graduated from the Woodstock Medical College in the class of 1848.

Correspondence.

SECOND ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(From Our Special Correspondent.)

HEALTH SUPERVISION OVER PROSTITUTES—TRIALS OF THE HEALTH DEPARTMENT—HOSPITAL AND PRISON SERVICE—AMEBIC DYSENTERY—CLIMATE OF MANILA—MEDICAL LABORATORY WORK—CHINESE MEDICINE—RELAPSING FEVER—HISTORY OF PLAGUE IN THE PHILIPPINES—ELECTION OF OFFICERS.

MANILA, March 15, 1905.

THE third session of the association took place promptly at 4 P.M., March 3. The first paper read was by Dr. E. C. Shattuck of the Board of Health, upon "The Treatment of the Venereal Diseases at the Sampoloc Hospital." It has been the custom to exercise supervision over the prostitutes ever since the American occupation. Regular examinations are made by a medical officer, and any prostitute who is found to have gonorrhea or syphilis is sent at once to the hospital, where she is detained and treated until she is no longer a source of danger to her patrons. In the case of gonorrhea this is determined by the examination of slides made from the secretions of the cervix and urethra. These slides are examined by independent observers at the laboratory, and whenever they are reported as being negative upon two examinations in succession, made on different days, the patient is discharged. He said that the average number of days in hospital was being gradually reduced. This was attributed to the fact that the cases probably now came under observation earlier and therefore yielded more readily to the treatment.

The next paper, "Measles," by Rudecendo Cuervo, M.D., was read in Spanish. It was an exhaustive study of the history of the disease and was very favorably commented upon.

The above was followed by an "Address in State Medicine," by Major E. C. Carter, U.S. Army, Commissioner of Public Health. He prefaced his remarks by stating that the result of his three years' work in the Philippine Islands, in connection with the Health Department, was one of the greatest disappointments of his life. It seemed to him that it had been one series of failures. It was his intention, he said, to begin with a brief summary of the conditions that confronted the Board of Health in the summer of 1902, and to end as best he might by leaving the questions suggested rather than raised by his paper, to be discussed both by the members of the association and perhaps by the writer himself, at some future time, when he might command more leisure and be at a happy distance from the scene of his trials, disappointments, and failures. If the scientific aspect and purpose of the work were considered alone, justice could not be done to the devoted men who have given their best to sustain the Commissioner of Public Health in his endeavors to meet emergencies and to pursue the golden mean, albeit a compromise between the right and the expedient. It was not to be denied that this so-called mean has been nearer to the expedient than to the scientific; and that which has been accomplished has been brought about along the lines of least resistance, rather than along the lines of scientific accuracy. For it has been demonstrated here, as elsewhere, that state medicine or prophylactic sanitation must be largely influenced by the habits, customs, etc., of the particular people whose condition it is desired to improve. A knowledge of the sentiments of a strange people is not obtained from books nor from observation alone, and from the lack of such knowledge he often found himself in deep water, from which he had not always escaped unscathed. It was hoped that, by formulating in advance a clear, concise, and definite plan, the people could themselves be persuaded, led, and finally attracted toward the good. He said that if the history of the Teutons and of the Latins taught anything it taught that the systems of life are a growth and development, and do not spring admirable and complete from the brain of some genius, as Athene sprang from the forehead of Zeus. The effect of epidemics and the violation of sanitary laws has been more disastrous upon nations and peoples than war. The plague at Athens destroyed Greek culture and civilization as much as did the Peloponnesian War or the loss of the Athenian fleet before Syracuse. The insanitary [illegible] a nation's worth is gauged by its sanitation, the people's efficiency by their life hygiene, and that doom is predicted by dirt and destruction by filthiness. He spoke of the satisfactory result of vaccination in the city of Manila, and pointed out that there were only 27 deaths during 1904 from smallpox, 10 of which occurred among Europeans and Americans who had neglected or avoided vaccination, and that the latter number was out of all proportion to the number of natives affected. Referring to the cholera epidemic, he said that he had felt compelled to write to his chief at Washington that all precautions against the spread of the epidemic were doomed to failure and that its end might be expected only when the vulnerable material was exhausted. The epidemic had taught the following lessons: 1. Recognize cholera at the beginning; this is not difficult clinically and microscopically. 2. Acknowledge it frankly and control it in its incipiency by heroic measures if necessary. 3. Provide stores and comforts for the sick. 4. No method of treatment is satisfactory save, perhaps, serum. 5. Cholera is a disease that may be controlled and confined. The worst condition that confronted the Board of Health in the epidemic of 1902 was the partly active and the partly passive hostility of the medical profession.

The next paper was read by Dr. R. E. L. Newberne, on "San Juan de Dios Hospital." This was an interesting history of a Manila hospital, which is located in the walled city and was built in the year 1595. It has always been under the direction of the Catholic church, being first in the hands of the Brotherhood of Santa Misericordia, and finally was jointly under the management of the Brotherhood of San Juan de Dios and the Sisters of Saint Vincent de Paul.

The next paper, "The Medical Department of Bilibid Prison, and Some of the Interesting Diseases Among the Prisoners," was by Dr. W. L. Moulden, the prison physician. He gave a description of the manner in which the work is done. A separate building, situated in another part of the city, is used exclusively for the tuberculous cases. The insane are confined at the San Lazaro Hospital. All other cases are treated in the prison hospital. Beriberi is a common disease, but is usually only found among the new arrivals from the provincial jails. A great many surgical operations are done, particularly for hernia. With the exception of beriberi, the diseases encountered resemble very closely those found in similar institutions in the United States.

"The Metropolitan Police Medical Service," by Dr. A. T. Short, police surgeon, was the title of a paper, which gave a brief description of the medical aspects of the Manila police force.

The last paper read at this session was by Dr. W. E. Musgrave, the assistant director of the Biological Laboratory, entitled "Symptoms, Diagnosis, and Prognosis of Uncomplicated Intestinal Amebiasis (Amebic Dysentery) in the Tropics." The clinical symptoms were not at all characteristic, and might vary from practically none to all those found in gastrointestinal disturbances. A trustworthy diagnosis was not possible unless confirmed microscopically. The writer stated that all cases in which the ameba was found in the stools should be regarded as dysentery, and treated as such, regardless of the fact as to whether there were symptoms present or not. No one could at present state whether a given ameba was pathogenic or non-pathogenic. He said he knew of several individuals who frequently had amebæ present in the stools over long periods of time and no clinical symptoms had manifested themselves, yet these should be regarded as rare exceptions. It might be that these cases had small ulcers which it was impossible to detect, and that such cases might give rise to liver abscess. The prognosis of all cases seen early was excellent. In over 200 cases seen by him, only three were considered sufficiently grave to be sent to the United States for climatic reasons.

At the fourth and last session, Dr. W. S. Washburn delivered an "Address in Climatology." This was a most learned dissertation upon the theory and causes of climate. Many comparisons were made between the climate of the Philippine Islands and other tropical and sub-tropical countries. He proved by statistics that the climate of Manila was one of the most desirable of all tropical countries and more particularly that the white race could live here just as long as anywhere else in the world. He said that the death rate here among the whites was as low as any given for the most healthful cities of Europe or the United States.

The next paper, "The Care of the Aged and Infirm," by M. Gomez, secretary of the Board of Health, was read in Spanish.

"Evolution of the Medical Laboratory Work in the Philippine Islands, and Opportunities Now Offered for Future Work," by R. P. Strong, director of the Biological Laboratory, was a brief history of what has been accomplished since this work began. He stated that the work had had a great economic value, in that many of the serums, vaccines, etc., were made by them, and that chemical analysis, protography, and microphotography, assaying, etc., were done for the entire Insular government. He desired to invite particular attention to the fact that free laboratory facilities were now at the disposal of any reliable person from any part of the world. Space would be cheerfully given, chemicals and materials provided, and all necessary experimental animals supplied. The only condition imposed was that the result of such work should be published

in their laboratory bulletin. There would be no objection to the publishing of the results elsewhere in addition. He called attention to the wealth of material from which to choose, mentioning particularly plague, dysentery, surra, rinderpest, glanders, malaria, dengue, etc.

The next paper, "Chinese Medicine," by Tee Han Kee, easily attracted more attention and excited more interest than any other paper read at the meeting this year. He said that the history of Chinese medicine dates back as far as 3000 B.C., and may be divided into three periods. (1) The dark age, which dates from the time of Emperor Sin Long, down to Confucius, a period of about 2280 years. (2) The progressive age, which dates to the time of Emperor Shun Ti of the present dynasty, a period of about 1,800 years. (3) The retrograding age, which dates from Emperor Shun Ti to the present time, a period of 268 years. The first period is renowned for the discovery and use of many different drugs, and also for the first medical book ever written. The first man in China who ever understood medicine was Emperor Sin Long. He was an inventor, agriculturist, philosopher, and particularly a physician. He wrote the first work upon therapeutics. For many years his works were the standard textbooks for the succeeding generations. The second period was celebrated for its many famous physicians and surgeons. Cases of amputation at the shoulder-joint are recorded. A case that particularly attracts attention is the operation performed by Wah To on the Chinese general, Kwang Hu Choo, who was advised to have the operation performed with an *anesthetic*, but he preferred to divert his mind with a game of chess while the operation was being performed. Inoculation for smallpox was practised by wearing the clothes of a person who had died of the disease, by placing fluid from the pustules in the nose, by blowing pulverized scabs directly through the nostrils, or by inserting with them moist cotton and keeping them in position for five days. During the third period, or retrograding age, the physicians became selfish, and allowed their knowledge to die with them. The practice of Chinese medicine is not conducted upon a scientific basis at present. It is either learned by apprenticeship, in which case the master does not teach all he knows for fear of competition, or a few medical books are obtained and the person starts into practice. The therapeutic value of drugs is pure guesswork. No autopsies are performed upon human beings, the meager knowledge of anatomy being derived from animals. Disease is classified as either a hot disease or a cold disease. Hot diseases require cooling drinks and cold ones require hot drinks. This permits the layman to argue with the doctor upon an equal footing. Diagnoses are made by feeling the pulse, which is sometimes an operation of several hours' duration. The radial artery is always used for this purpose and the wrist is divided into three parts, the pulse of each of which corresponds to particular organs of the body. The study of the pulse is made from a book, which is called the book of eighty-one difficulties. Anatomical descriptions are vague and indefinite. Organs are described as consisting of blood and air; the heart, for instance, is said to be in front of the fifth vertebra, is attached to the trachea, and contains more air than blood and is the seat of hearing and taste. The gall bladder contains more blood than air and controls the will power. He expressed the opinion that modern medicine would gradually force its way into China. Already the great relief which is obtained from many of the surgical operations has made a great impression upon the Chinese.

Dr. Koch of Hong Kong read some notes on four cases of "Relapsing Fever," discovered in Hong Kong during the month of January last. These cases were found among some smallpox suspects, but as the fever went out, and no eruption appeared, it was decided to examine the blood, whereupon the characteristic spirilla of Obermeier were found. These are the first cases ever reported in Hong Kong. They occurred among some Chinese sailors who had recently come from India. Dr. Koch said that the disease is transmitted by mosquitos or possibly bedbugs. Experiments upon monkeys are now being conducted, the result of which will be published later. His office boy, who had been detailed to keep the mosquitos from the patients but who did not come in contact with the patients nearly so closely nor for as long periods as the nurses, contracted the disease. The incubation period in this case was three days. Quinine, large doses of carbolic acid, and various treatments were tried but none of them seemed to have any effect upon the disease. One of the patients died. Blood specimens taken from the spleen and at a number of other places did not show the presence of the spirilla.

"Disinfection of Ships," by Dr. J. D. Long of the Public Health and Marine Hospital Service, was read by title only, owing to lack of time. "The Military Medical Service in the Philippines," by Maj. Charles Richards, Medical Department, U. S. Army, was also [illegible] papers are to be read at the next [illegible] Medical Society. "Infant Mortality," by Dr. Luis de Castro, was read by title only.

"A History of Plague in the Philippine Islands," by Maximilian Herzog, pathologist of the Bureau of Laboratories, was the next [illegible] paper read at the meeting. [illegible] plague which [illegible] there is any record was reported in Manila, December 26, 1899. The author was of the opinion that the disease must have been present before that date, but that it was not recognized. He referred to the greater susceptibility of the Chinese to the disease; next came the Filipinos, the least susceptible being the whites. There has, however, been a steady decline in the percentage of cases among the Chinese; this he ascribed to natural causes rather than to any measures that were taken.

At the close of the scientific session a business meeting was called. Among other routine business transacted was the passage of a resolution authorizing the standing committee to name the time and place of the next annual meeting. At the election of officers, the following were chosen: *President*, Maj. E. C. Carter, U. S. A.; *Vice-presidents*, Dr. Victor G. Heiser, Public Health and Marine-Hospital Service, and Dr. Rudecendo Cuervo; *Secretary-treasurer*, Dr. R. E. L. Newberne; *Councillor*, Dr. R. P. Strong. The meeting then adjourned *sine die*.

At 8 P. M. a banquet was given at the Army and Navy Club. It was well attended. Among the guests were the Governor-General, Luke E. Wright, and other prominent officials of the Insular Government, the Army, and the Navy. Many witty speeches were made and the evening was spent in a very agreeable manner.

The second annual meeting was a success in every way. The attendance exceeded all expectations, averaging over one hundred for each meeting. The papers were of a high character, many of them being read by men who are acknowledged to be among the leaders of the American medical profession not only in the Philippine Islands, but in the United States as well.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S FUND—PROTEST AGAINST SIR MICHAEL FOSTER'S OPINIONS—MILK SUPPLY AND STERILIZATION—INFANT FEEDING—EDUCATIONISTS AND DEGENERACY—BISMUTH—QUEEN'S JUBILEE HOSPITAL—VARIA.

LONDON, March 31, 1905.

THE Prince of Wales presided on Wednesday at the annual meeting of the King's Hospital Fund, and gave a lengthy address which contains a lucid exposition of the position and needs of the fund. He touched on the various questions that have had to be considered during the year, such as economies in hospital administration, the relations of hospitals and schools, the amalgamation of small or special institutions, and so on. He announced that he was authorized to express the King's entire satisfaction at the results achieved during the year. The income of the year was £85,200, but of this £4,000 is accounted for by the unexpected increase in the sum received from the League of Mercy, viz., £14,000, against £10,000 in 1903. The Prince expressed gratitude to the workers in that valuable auxiliary which gathers up small sums for the fund. For the future he hopes eventually to realize the £150,000 a year—the income which the King from the first hoped would be reached, although the last year's total receipts only amounted to £84,000. Still £80,000 has been distributed, and considering the depression that has prevailed and the numerous claims on the benevolent, that is a noble sum to have been raised.

Sir Michael Foster has shocked the profession and gone far to forfeit authority as a physiologist or scientific thinker. Can it be that having entered parliament he has so soon degenerated into a mere partisan politician? At any rate he has drawn upon himself a reproof for his "distortion of scientific reasoning," "misuse of physiological expressions of facts," "false assumption," "sophistry," "misleading reference," "grave error," "confusion of ideas," and so forth. These expressions and others as emphatic are contained in a protest signed by Sir W. Broadbent, Sir T. Barlow, Sir Victor Horsley, Mr. P. Gould, and half a dozen other eminent leaders, against a memorandum by Sir M. Foster issued by the Board of Education. You will remember that some time since a petition was presented to that board, signed by nearly 15,000 practitioners, in favor of teaching elementary hygiene and temperance in Board schools. A deputation of leading medical men waited on the president of the Board to urge that the petition should be granted, and a general impression prevailed that this must be the case. Now, however, the Board has issued a document containing an adverse memorandum by Sir M. Foster and the Board's remarks thereon. Sir Michael's memorandum is devoted to criticising certain syllabuses

which have been to some extent used in schools, and he unquestionably makes statements which well deserve the condemnation so vigorously administered. For instance, he says that if alcohol is to be spoken of as a poison so should be oxygen and water. Could anything be more misleading or more puzzling to school children? He speaks of the effect of "water applied directly to the nerves," as if such a physiological experiment on an exposed nerve has anything to do with the effects of water or alcohol taken into the stomach. Is it too severe to say that by such sophistry "scientific truth is perverted and the issue completely confused?" Sir Michael has evidently confused and misled the Board, for in their remarks they complain that "oxygen in the syllabuses is regarded as an essential of life. No mention is made of any dangerous properties." One would have supposed that the Board would have been able to raise enough common sense among them to laugh at the pretentious nonsense of oxygen and water being poisonous, and knowledge enough to tell their advisor that without this oxygen in the atmosphere we should all perish, and that the effects of a pressure of five or six atmospheres is quite "another story." One more sample: Sir Michael refers to intoxicants and intoxicating, using the words in the technical sense, and so says both tea and alcohol produce intoxication. Fancy telling the school children this, and when they ask the meaning of the word are told drunkenness, what would be their idea of the teacher's truthfulness.

The signatories of the protest followed it up by calling a conference of medical men, which was held on Friday in the Examination Hall, on the Embankment. There was a large attendance, and the leaders of the profession were numerously represented. Sir Wm. Broadbent presided, and speeches were made by Sir T. Barlow, Sir V. Horsley, Dr. Wm. Collier, Dr. Robt. Jones, Dr. F. W. Mott, Mr. McAdam Eccles, Mr. Pearce Gould, Professor Sims Woodhead, Dr. Hyslop, Dr. Harford, Dr. Symes Thompson, and Dr. Ridge, and the meeting showed strong disapproval of Sir M. Foster's contention. The chairman insisted that the physical degeneration of which so much has been said, depended largely on ignorance and vice, and should be counteracted early in life. Sir Victor Horsley said that the teachers had been misinformed as to the object of the profession, which was to secure attention to hygiene, and surely bodily health and healthy homes deserve as much attention as geography or history. Dr. Robt. Jones, of the County Asylum, showed the evil effects of drink, as shown in the report of the Committee on Deterioration, which states that the evidence convinces them "that the abuse of alcoholic stimulants is the most potent and deadly agent of physical deterioration." Sir T. Barlow referred to the great change of opinion as to the place of alcohol during the last fifty years, and said that its value was still greatly overestimated by many. It was no longer thought necessary as an article of diet, but further observation showed that those who took it more easily fell victims to cholera, pneumonia, and other diseases. Mr. Eccles urged that the dissemination of sound knowledge on the subject was to be encouraged in every way, and that in view of the many questions they would have to meet, medical students should receive the fullest instruction thereon.

Sir Shirley Murphy presided over a meeting of the Royal Sanitary Institute on Saturday, when a discussion on municipal milk depots and milk sterilization was opened by Dr. G. F. McCleary. He said there was no necessary connection between depots and sterilization, and no need to limit the operations to a single costly method of supply. Yet milk specially prepared for infants was the only kind supplied in the ten municipalities which had established depots. The object was to reduce the heavy infantile mortality resulting from improper feeding. Mothers' milk was immeasurably better than anything else, but unfortunately the natural food was not always available. He described the methods adopted in Rochester, U. S. A., and expressed the opinion that municipal depots should supply, not sterilized, but clean, milk from their own cows, strictest aseptic conditions being insisted on in all departments. Dr. Groves declared women should not be allowed to have children unless they gave the State a guarantee to nurse them(!) He did not say how that could be accomplished. Dr. Cooper Patten was a trifle more practical. He said the discussion was only a heresy that should be extirpated, and mothers encouraged to develop lacteal secretion, but he did not say how. Dr. Robertson, of Birmingham, greatly preferred natural to sterilized milk. Dr. Walford, of Cardiff, protested against the waste of ratepayers' money in undertakings which were only carried on at a loss, and said the proper course was to place all dairies under medical control. Dr. Manchester said the municipal depots did not deserve all the credit they claimed. Dr. Sykes pointed out that they could not teach young girls all the details of nursing, but they might instruct mothers in all classes. Several other medical officers of health spoke, and a vote of thanks was passed to Dr. McCleary, who in the afternoon received the visitors at the Battersea depot, and afterwards entertained them at the Town Hall.

On Wednesday, Dr. W. G. McDowell, lecturing at the Institute of Hygiene, said that the common ideas as to feeding infants in their first year were quite wrong. There was a craze for superfatting their milk, and though the infants at first grew plump they early developed obstinate constipation, and finally suffered from convulsions, for the extra fat was not digested. They recovered when the fat was reduced by skimming the milk, but too often the opposite plan was tried—more cream was added, and the child lost. Teething was constantly blamed, but if the mother thought first of the stomach, of fresh air, or heredity, she would be more likely to consult her doctor before it was too late. The lecturer further protested against preservatives being permitted. To let the dairyman substitute boric acid for cleanliness and thoroughness was iniquity. He quoted the record of experiments with boric acid on cats from the September issue of the *American Journal of Medical Science*, to show the work of repeated doses on young children.

The degeneration of the race, according to some faddists, has reached such a pitch that the nation is in danger of extinction in the coming generation. Between feeble-minded, underfed and unfit children, what is to be expected, ask the educationists, unless their warnings arouse the people to insist on free instruction from the lowest school up to the highest university position, with free food, free clothing, and free housing for all who ask for it? But where is the money to come from? says one; throw it on the rates, reply the fanatics. It is not surprising that a continental lady visiting a school, and asking all children who are hungry to hold up their hands, should be deceived by the response. But we might have expected Sir J. Gorst and Mr. Macnamara to have displayed a little common sense and not to have rushed off with the lady to protest to the Board of Guardians that they had failed in their duty, and that the children of their district were starving! But in spite of refutation, the fanatical educationists pursue their one notion in and out of parliament, and provide sensation papers with shocking warnings of the decay of physical and mental power. A proposal to drill the school children might have been supposed to meet their approval, but Sir John Gorst declares the military system "totally unsuited to the tender and delicate muscles of young boys and girls." The poor law as now administered provides for every destitute person, and parents who cannot feed their children can always have relief. But politicians of the caliber of Sir J. Gorst and Mr. Macnamara say that would lead to the poor parents being disfranchised—as if hungry men and women were more anxious to vote for these gentlemen than to get a good meal.

The matter has been before parliament in various forms. Sir J. Gorst produced a little sensation by reading a letter from a lady describing the children in a northern town as unwashed, in rags, and half starved, but often kept from school to exercise the well-groomed, well-fed dogs of their fathers. And yet he did not seem to see that such fathers should be compelled to do their duty, rather than that honest rate-payers should be mulcted to supply their deficiencies. The government declined to introduce a bill on the subject, but a private member has used his fortune in the ballot to do so.

Dr. H. A. Caley lately contributed some interesting observations on bismuth to the Therapeutical Society. The local action on the stomach he regarded as the most important, and the carbonate as the salt most generally useful and to be preferred as a gastric sedative. As to the action in intestinal disorders, Dr. Caley advanced some experimental evidence as to the antiseptic action of the salts of bismuth. He found the subnitrate had a distinct germicidal action on cultures of the bacillus coli; the salicylate had a similar effect, but much weaker; the carbonate was inert in this respect. Under laboratory conditions the antiseptic action was destroyed by alkalies, though clinically this cannot be, for alkaline media are quite effective. It may be inferred that the chief action in the intestines is local on the mucous membrane, and the indications for its use catarrhal inflammation. In large doses, bismuth may replace direct intestinal antiseptics, astringents, and opiates. For this purpose subnitrate is the preferable salt, and if a stronger astringent is desired catechu may be added, and this combination is better than the subgallate.

The annual meeting of the Queen's Jubilee Hospital was chiefly occupied with an attempted explanation of the dispute which led to the resignation of the staff and the withdrawal of the promise made by the Princess Louise Augusta of Schleswig-Holstein to lay the foundation stone of an extension. It was said that one of the staff informed the Princess that the extension was only to be an addition to the ground floor. The committee passed a

vote of censure for this, and the whole staff resigned, and a still larger staff was appointed by the committee in the course of a few days. Of course the old staff do not join in the so-called explanation, and I hear of other causes of dissatisfaction which they might have anticipated when they joined, and which the new men who rush into the vacancies may perhaps experience.

The Lincoln epidemic of typhoid is declining. The notifications for the week ending the 24th numbered 32, as against 46 in the previous week.

The Medical Society has awarded its Fothergillian prize for 1905 to Sir F. Treves.

A deputation from the London and Liverpool schools of Tropical Medicine waited on the Colonial Secretary on the 22d inst., in reference to beriberi and sleeping sickness.

The army council has given up the plan of providing soldiers with artificial teeth.

The government is sending a scientific expedition to India, to investigate the origin and cause of plague. They have wisely entrusted the direction and arrangements to the Royal Society and the Lister Institute.

A meeting is to be held at the Royal College of Physicians, on the 10th proximo, to consider the question of the amalgamation of the societies. The president has promised to take the chair. The question has been discussed at intervals for about a century, so there ought not to be need of much further talk about it.

Mr. Beit has increased his donation to the proposed Institute of Medical Sciences of the University, to £25,000.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

MORTALITY STATISTICS IN PRUSSIA IN 1903—TWENTY-SIXTH ANNUAL MEETING OF THE BALNEOLOGICAL SOCIETY—ANTI-STREPTOCOCCUS SERUM—CARDIAC WOUNDS AND THEIR TREATMENT—APPENDICITIS—ELECTION OF OFFICERS FOR THE VIRCHOW HOSPITAL.

BERLIN, March 30, 1905.

THE greatest triumph for medical science is the decrease in mortality. The mortality statistics of Prussia for 1903, with the causes of death, have just been published. Of 707,950 deceased, 14 died of smallpox, one—the Berlin physician who contracted the disease during his experimental researches of plague. Anthrax was the cause of 12 deaths, glanders of 3, insanity of 8. Of 10,000 people, 28.08 died of digestive disorders; of old age, 20.92; of tuberculosis, 19.70; of pneumonia, 15.25; of diseases of the nervous system, 12.21; or cancer and other neoplasms, 6.59; of diphtheria, 4.9; of whooping-cough, 3.28; of measles, 2.73; in childbed, 2.28; 0.86 of erysipelas and other wound infections; 0.87 of typhus. The data as compared with those of other years are very instructive. A striking fact is the remarkable decrease in the number of deaths from wound infections, as well as from typhoid fever and the other so-called contagious diseases. This is without question the best proof that modern hygienic measures are scientific. In this relation it must not be forgotten that animal experimentation is most important in revealing the secrets of contagious diseases.

The twenty-sixth annual meeting of the Balneological Society was held in Berlin from March 9 to 13. I shall refer briefly to a few of the many papers that were read at that time. Heubner said that from experimental investigations his conclusion was that salt baths increase the process of decomposition of albumin in the body; that these baths are weakening to children; and that sea-bathing must be controlled by physicians in the future. Burwinkel (Nauheim) advocated periodical bleedings in arteriosclerosis in connection with the iodine and digitalis treatment. Grawitz (Berlin) preferred in the treatment of anemia the use of inorganic iron and an abundant vegetarian diet. Winternitz (Vienna) did not believe in the short cold baths in fever, recommending rather the longer baths of moderate temperature, especially in typhoid fever. Eulenburg thought that the treatment of functional and organic diseases should differ—that only the former could be cured by balneotherapy. Sea-bathing was for patients who were not too much weakened by disease. Koblauck advocated the use of cold baths in functional diseases of the female sexual organs.

F. Meyer's paper, entitled "Ueber die klinische Bedeutung des Streptococcenserums," aroused great interest, because it afforded the opportunity of listening to the discoverers of the serums—Meyer, Aronson, and Marmoreck. Meyer does not believe that it is justifiable to use his serum in any but cases which are otherwise hopeless. He advises a dilution of the serum in proportion to the effect which is looked for. The serum protects the organism in angina, erysipelas, and scarlatina. It cures cases of sepsis. It takes only from 12 to 20 hours for the effect to be noticed. For 24 hours there is a violent reaction, and then the disease begins to give way. The injections are indicated in ulcerating processes of the serous membranes, in tuberculosis, and in rheumatoid polyarthritis. Cutaneous inflammations and albuminuria are seldom noticed. Aronson advocates the use of his serum in those cases which are not suitable for Meyer's serum, and rejects the dilution of the serum. Marmoreck has used his serum since 1896, and has seen no ill effects from it, especially no rise in temperature. He thinks it can be used without limitation. He attributes the good results to the method of production of the serum and to the use of small quantities.

The great number of cases reported by Borchardt in his paper on cardiac wounds, which was read before the medical society, made the address of great importance. In one group of cases are those in which death occurs at once from the great force of the projectile, which causes a rupture or divulsion of the heart. In the second group of cases death occurs from hemorrhage—sometimes from the pressure of the blood which collects in the pericardium. After the diagnosis is made the heart must be exposed and the wound, as well as the pericardium, sutured. In some cases a small drain is introduced. Of 61 patients treated in this manner 24 recovered—39 per cent. Karewsky's paper on appendicitis was read at a meeting of the Society for Internal Medicine. He differentiates between appendicitis, *i.e.* inflammation of the appendix, and the perityphlitic attack. Foreign bodies seldom enter into the etiology. The most frequent cause of the disease is an enterocolitis. The prophylactic treatment consists in careful attention to the condition of obstipation and gastroenteritis. On account of the distribution of the nerve supply of this region, the pain may be felt in various localities. The most significant symptoms are the pain and tenderness on pressure in the ileocecal region and the extreme gaseous inflation of the cecum. The chronic type should be treated by rest. The expectant treatment should not last longer than from four to six weeks. The writer believes the best remedy to be operation.

Three officers have been elected for the new Virchow Hospital. Goldscheider is chief of the internes, while Hermes holds the same position over the externes. Both of these men have until now been in the Moabit Hospital. The chief is Ohlmüller, who till now has been in the Reichsgesundheitsamt. This is the first time in Berlin that a physician has been appointed chief of the department of administration in a hospital.

THE OSTEOPATHIC BILL IN THE NEW YORK LEGISLATURE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: The latest report I have seen in the daily press as to the status of the Osteopathic bill, now before the Legislature at Albany, was to the effect that it had been advanced and that the opposition to it seemed to have fallen off. Is it possible that the medical profession of this pivotal State of the Union is indifferent to the persistent efforts of this aggressive aggregation of masseurs to compel unqualified legal recognition in this State? Have we taken the pains to state the case fairly and frankly to the members of the Senate and Assembly, so that they can vote understandingly on this or any other similar bill? Perhaps all has been and is being done that can be done in the matter, but it seems to the writer that it is due to the honorable legislators that our attitude as a dignified profession should be clearly stated, together with a truthful picture of the results on the welfare of the community which will inevitably follow the passage of the proposed bill. Perhaps this can be done in no more effective way than by a candid analysis of the character and claims of those who demand this legislative recognition.

The founder of this "school," whose shrewdness, assurance, and power to influence his followers are too much in evidence to be disputed, claims that his "system" of modernized massage is based on an anatomical astuteness and exactness that leaves Gray floundering in the shadows of antiquarian amateurishness. His now quite numerous and steadily multiplying disciples, we must admit, are presumed to be drilled with more than ordinary thoroughness in regional and relational anatomy, and in a strenuous but by no means new system of manipulations and special massage.

The leaders of this new craft lack the necessary groundwork of thorough rudimentary education, and perspicuously display their want of that general grasp of science which keeps men out of the ruts of intellectual narrowness and petty prejudice, and enables them to compel the respect and confidence of the world. They are asking for special privileges and class legislation. What they need is class education. When they make themselves and their pupils competent to safeguard human lives and to diagnose accurately diseased conditions and to comprehend their import they

will have no difficulty in passing the most exacting Boards of Examiners throughout the country and will not be obliged to ask any favors at the hands of any of the established schools of medicine. Nor will they be restricted to any line of therapeutic practice. They will be perfectly free to use any method or material, manipulation, or process that suits their fancy. Every legalized practitioner has this unquestioned right, and they would then compel recognition of themselves as legalized practitioners. To ask to be recognized without this substantial and necessary knowledge of the human system and of the natural, chemical, physiological, and psychic laws that affect and control human life is entirely unreasonable. For any legislature to yield to their sophistical reasoning and their persistent importunities is not only unjust to those who have made themselves thus competent, but it is tampering with human life, menacing the safety of the community.

It may be added in behalf of the younger followers, many of whom are not too full of conceit and self-satisfaction to realize that in order to win permanently they must begin at the foundation, acquire a solid education in all the collateral branches of medical and surgical science, and thus become competent to hold their own with the most eminent practitioners of any school, instead of being content to be looked upon as merely expert masseurs, that substantial accomplishments never long go begging for substantial acknowledgment, and when these aspirants for public favor and patronage genuinely "get down to business" on this basis they will no longer need to fight for legal recognition.

Our legislators are called upon to see that the laws favor no special class, that all are placed on an equality, and held to the same substantial requirements, which is neither more nor less than

FAIR PLAY.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 13, 1905.

Cancer in and about the Mouth.—F. C. Cobb insists on the importance of early diagnosis of malignant disease in this general region. Lesions are of two classes: (1) those which, benign in themselves, may undergo a degeneration into malignancy, such as leukoplakia, warts, ulcerations, fissures, and tubercles, and (2) those in which clinical manifestations are already evident. Special attention is given by the author to leukoplakia, which so often degenerates into epithelioma. The process may be prolonged for twenty years before actual cancer forms. Great care should be exercised in determining the cause of buccal ulcerations, especially those around the edges of leukoplakia areas. Lupus and tuberculous ulcers can be diagnosticated by the wide shallow appearance of the area involved, with its undermined, irregular edges, and lack of induration. In cases which may suggest syphilis, the therapeutic test may be employed, and in a week we are generally able to determine whether the diagnosis of specific disease is correct or not. If it is decided that the process is a malignant one, a radical operation should be undertaken, a small wedge being removed at the time of operation and examined by a competent pathologist before proceeding further with the operation. If, on the other hand, any reasonable doubt exists as to the nature of the growth, the same procedure —namely, excision of a small wedge-shaped piece—may be practiced under cocaine, taking care to cut wide of the lesion into healthy tissue, both to avoid any danger of starting metastases by the incision and also to afford the pathologist a comparison between the healthy and diseased tissue. The edges of the wound are brought together by suture and unite very quickly. No time should be lost in examination of the piece so removed, and if malignant, radical operation should follow as soon as possible.

The Use of the X-Ray in Post-Operative Treatment of Cancer in the Mouth.—This topic is discussed by E. A. Codman, who gives his experience in several instances. These have been in a general way discouraging, yet the author states that he feels like saying to an inoperable, hopeless patient that the measure is worth trying. Treatment of operable cancers in the mouth by this means the author regards as unjustifiable unless the circumstances are extraordinary.

New York Medical Journal, April 15, 1905.

Cases of Enteroptosis and Cardioptosis, with Return to the Normal.—The details of six cases are given by Max Einhorn. They illustrate the fact that a complete return of prolapsed organs to the normal is possible, and also the fact that an increased bodily weight conduces to a better position of the organs. It is somewhat difficult to explain the latter fact. It may be that it is due to increased deposit about the viscera, especially the heart and kidneys. The former viscus is the first organ to return to its normal position. A return to the normal seems to be more frequent in cardioptosis than in ptosis of the other viscera. The treatment in all these cases consists mainly in the wearing of a properly fitted abdominal belt, and ample feeding. The latter is the more important of the two. Even if the organs do not return in every instance to the normal position, subjective symptoms are generally relieved by the routine above indicated.

Erythema and Urticaria, with a Condition Resembling Angioneurotic Edema, Caused only by Exposure to the Sun's Rays.—The patient of S. B. Ward was an American single woman, aged 27 years, who suffered from an eruption every time she was exposed to the sun's rays. On one occasion she exposed her shoulders, chest, and arms to oblige the physician, who was at hand to note the immediate effects. After sitting five minutes in the direct rays of the sun, the areas above enumerated were of a uniform brilliant scarlet color as if the subject of scarlet fever. The skin was swollen to such an extent that there was some impediment to flexion at the elbow joint. The hairs all stood up straight, in marked contrast to the other arm, and the sensation of burning was complained of as intense. The condition was manifestly one of erythema. On parts of the arm, and especially on the front of the chest, there were present also about a dozen white, round wheals, like those of urticaria, varying in size from a large pin's head to a silver dime, accompanied by marked itching. These conditions of redness and wheals extended in a less degree downwards below the line of actual exposure, under one layer of thin linen. Fifteen minutes later, the redness of the arm and burning sensation had markedly diminished, but the swelling was about the same, and the depressed orifice of every sweat duct was perfectly visible. On the front of the chest the redness had disappeared, the wheals had run together, and one large white patch, irregular in shape, some five inches long and two inches wide, showed the pores most plainly. The face, neck, and hands were of an almost uniform red color, somewhat blotchy, save that the neck showed a band of normal skin about two inches wide which had been protected by the shadow of the head; in other words, the parts of the skin usually exposed did not show the changes nearly as plainly as those that were usually covered. Tactile sensation and the perception of heat and cold were perfect. The conjunctiva of the left eye was injected, the small vessels becoming visible. After the lapse of an hour the skin everywhere resumed its normal appearance, except that on the front of the arm the capillaries remained dilated, but the sensations of burning and itching were all gone. These changes are referable to a vasomotor disturbance. If the exposure was short an erythema would appear; if longer, urticarial wheals, and if still longer, an angioneurotic edema.

Medical News, April 15, 1905.

Intracranial Traumatic Hemorrhage.—The subject is considered in a systematic way by J. S. Wight. The cases may be divided into epidural, pial, and cortical. Epidural hemorrhage may come from the diploic vessels, and is usually scanty. It may come from the dural vessel, espeally the branches of the middle meningeal artery, and is generally profuse and alarming. An osseous fragment may injure the dural sinuses, but the coagula are less abundant here, since the fragment causing the injury often closes it until disturbed by intervention. Pial hemorrhages may appear as punctate extravasations, but more often as a thin sheet over the vertex. If abundant, they may break into the arachnoid space. Cortical hemorrhages may result from wounding of the brain substance, which may be superficial or subcortical. If no cortical lesion can be discovered following an injury, a given hemorrhage may be due to a coincident traumatic apoplexy, or one following shortly after or long after. Hemiplegia as a symptom of the general condition may be, to be of value as a diagnostic symptom, well-marked, slight, or temporary. Monoplegia or paralysis more marked in one limb than in the other is a very rare condition, as the area of hemorrhage generally extends over the entire motor field, causing a diffuse pressure. General paralysis is another rare condition which may be explained by a very large clot, *e.g.* on the left side, rapidly effused and making pressure through the left side of the brain upon the right as well, or by coexisting extravasation into the brain itself. Absence of any paralysis is due to the effused blood finding its way through a fracture in the skull beneath the scalp. Limbs rigid, convulsed, or twitching is probably due to contusion of the brain substance at more spots than one. Clinical reports are given illustrating the various types of cases.

The Significance of Epigastric Pain.—A. M. Pond gives a general view of the symptoms of the common affections of the stomach with special reference to pain. The pain of ulcer gives a history of long duration, is usually in women under thirty, is frequently associated with vomiting of blood, or the passage of blood in the stools; the pain can be located by pressure, and the nervous symptoms are

pronounced. The pain is almost continuous, and extends over a long period of time, is increased by taking anything acid or saccharine into the stomach, and is relieved by taking bland food, or sometimes water, during the pain occurring between meals. In disturbances of impaired motility, the age is not so conspicuous a symptom. The pain is not so constant, there being intervals when comparative good health is enjoyed; it is dull and oppressive, more than acute. There is no history of nausea, in fact, vomiting is very hard to accomplish. The vomitus never contains blood or bloody streaks, but consists of yeasty ferments, a large amount of dark fluid, and undigested material. In carcinoma the pain is continuous; there is a rapid loss in weight, early cachexia, vomiting of bloody discharge, presence of a tumor, and rapid decline. In gall-bladder disease the pain is of a severe colicky nature, and, as a rule, is spasmodic.

American Medicine, April 15, 1905.

Hysterectomy for Fibroids of the Uterus, With a Report of 250 Operations.—John B. Deaver [illegible] experience with uterine fibroids has led him to hold the following opinions: Fibroids of the uterus do not require removal unless they are productive of symptoms, but that when they do become symptom-producing, they should be removed promptly, before the patient has been weakened by toxemia, hemorrhage, or sepsis. Abdominal supravaginal hysterectomy is the operation to be preferred in the vast majority of cases. Myomectomy is applicable only to younger women in whom the tumors are few in number and superficial in character. Panhysterectomy is to be employed only when intraligamentary growths, whether uterine or ovarian, render the performance of supravaginal amputation difficult or dangerous. The ovaries, or a part of one ovary, should be preserved in every woman who has not reached the age of menopause, unless they are distinctly and indisputably diseased or unless their retention would needlessly prolong and complicate the operation.

Paratyphoid Fever.—John Norman Henry says there are two varieties of paratyphoid fever produced by organisms which differ from each other only in minor cultural peculiarities. These two forms are difficult to distinguish either from one another or from typhoid fever. Of diagnostic importance in paratyphoid fever is the more abrupt onset and the earlier arrival of the acme of the disease as compared with typhoid. Otherwise the symptoms and course of these two affections may be similar, though the course of paratyphoid is usually shorter. Spots, splenic enlargement, nose bleed, hemorrhages, and a large number of complications may be present in these allied infections. The question of the possibility of a double infection of typhoid fever and paratyphoid has been raised by the presence in some cases of a double agglutination reaction of about the same degree of positiveness. Before this may be assumed as a certainty, however, it is necessary either to recover simultaneously both organisms from the blood of the patient suspected of being the subject of a double infection, or to saturate out the specific and group agglutinins of one infection and demonstrate the presence of the others. As yet these double infections have not been proved, though the saturation tests have not been applied to any great extent in these diseases. The pathology differs widely from that of typhoid fever, the autopsy findings being largely those of a septicemia. In some cases ulceration of the intestine has been found, but the ulcers have been of dysenteric type and Peyer's patches have altogether escaped. The mortality has been placed at about 6 per cent., being somewhat less than that of typhoid. Dr. Henry reports six cases.

Chronic Eczema as a Complication of the Senile Degenerations.—Medwin Leale says this skin lesion [illegible] initial onset during old age can usually be attributed to the circulatory changes, and their consequent degenerations. Usually it is an eczema erythematosum. The pathological changes in the skin are due to deficient nutrition, resulting in an alteration in the epithelial layers associated with dekeratinization in the upper layers, edema, and an immigration of exuded cells. After considering the symptoms and clinical picture of the disease, which he regards as purely a local manifestation of the circulatory and other changes, he states that although these cases often prove very resistant to treatment, yet in the majority more or less permanent cure, and [illegible] amelioration of the symptoms can be effected by care and perseverance in a rational line of treatment. He lays great stress on making a careful general physical examination, determining accurately the condition of the blood vessels, the lungs, kidneys, etc., and meeting any pathological condition by its appropriate treatment. The circulation should be properly maintained [illegible] carefully watched. Water [illegible] but in small quantities at a time, to secure rather a constant flushing, than an overdistention of the heart and blood-vessels. Moderate exercise is advantageous. The local treatment should have for its object stimulating and thereby improving the peripheral circulation of the blood and lymphatics. Carefully regulated and systematic rubbings and frictions best meet these conditions. Using the greatest amount of surface of the palms of the hands and fingers as can be well adapted to the affected surface, he adopts a combination of effleurage and massage a friction, the strokes of the hands following as nearly as possible the course of the veins and lymphatics. For lubrication a fine quality of olive oil is used, and with this for medication a pure finely powdered zinc oxide. Each application lasts from twenty to forty minutes, given every night, preferably just before retiring to secure sleep. Where more stimulation is necessary a strong tincture of pix liquida is used. Every second night before the application the patient is given a bath at 94° F., using a pure olive oil soap. Under these methods of procedure, if carefully followed, one may expect in most cases within from two to eight weeks a more or less permanent cure. He cites an illustrative case.

Pathology of Sciatica.—J. Ramsay Hunt records a typical case of sciatica with careful histological study of the affected nerve. To the naked eye the nerve trunk below the sciatic natch and in the popliteal space was swollen and distinctly enlarged. The swelling due to an accumulation in the perminol alveolar tissues of the translucent substance having the consistency of gelatine. A careful histological examination of the nerve by modern laboratory methods failed to reveal any structural changes of an inflammatory or degenerative nature. Hunt concludes that the so-called sciatica or, more properly speaking, sciatic perineuritis, is not an inflammatory condition in the usual acceptation of the term. That the underlying change consists of a structureless transudate into the lymph spaces of the nerve sheath of obscure nature and origin, but probably dependent upon or closely allied to the gouty and rheumatic diathesis.

Journal of the American Medical Association, April 15, 1905.

Abdominal Tuberculosis.—W. J. Mayo finds that tuberculous peritonitis is much more frequent in females than in males, and that the explanation of this fact may be found in the frequency of tubal infection. He has verified Murphy's observation of the patency and thickening of the tubes on one or both sides in these cases. In nearly all the peritoneal involvement was greatest near the infected tube, and this he attributes to proximity and not to gravity, as has generally been done. He explains the curative effect of laparotomy in these cases as acting in two ways: (1) by the mechanical separation of the fimbriated extremity of the tube from the surrounding tissue; and (2) after removal of the fluid, contact and adhesions with neighboring structures may wall off the infection from the general peritoneal cavity and enable nature to exert itself on a limited focus and to produce a cure. In some cases he has found appendiceal and not tubal infection as the cause. In the majority of cases, however, the localized focus of lupus of the tubal mucosa was the cause. He holds that the failure of laparotomy and evacuation of fluid in tuberculous peritonitis is due to reinfection from local lesions not removed, and in the mucosa of the fallopian tube, appendix or intestinal tract. In nearly every case the peritonitis has its origin in a local focus, primary or secondary, and, if the former, radical operation will largely increase the chances of its cure.

Relation of School Methods to School Diseases.—W. J. Herdman and J. H. McBride reported for the committee appointed at the New Orleans session of the American Medical Association. They gave an account of what has been done here and abroad in the way of school inspection and isolation of diseased children, and general sanitation of school buildings, the special care of backward children, etc. The report approves of the thorough psychological examinations made in the Chicago schools as the high-water mark in school inspection in this country and elsewhere. It finds the work satisfactorily done in a few places, though [illegible] inspection methods are far from complete in most [illegible] and in some they have not been tried. The report recommends that the American Medical Association put itself on record as urging complete and systematic medical inspection of school and school children; "(1) in the interests of the public, since it is a potent means for detecting and preventing the spread of contagious and infectious diseases; (2) for the purpose of securing to the child, while in attendance on school, the most favorable hygienic and sanitary conditions: (3) for the purpose of securing exact knowledge regarding the physical and mental capacities of each child, in order that the methods of instruction may be intelligently directed to meet individual needs."

Appendicitis.—Channing W. Barrett has analyzed the vital statistics of Chicago for the last fourteen years with special reference to appendicitis. He finds that it causes

about 1 per cent. of the mortality from all causes. The first consideration is an early diagnosis. All troublesome appendices should be removed without waiting for an acute attack, and all acute cases should be operated on without waiting for pus, rupture, adhesions or a possible interval. Perforation or gangrene with localized abscess should be operated on with drainage or removal of the appendix, according to the judgment of the operator, and operation is the more necessary if there is no walling off of the abscess. Acute appendicitis should be operated on whenever the patient's condition permits, unless he is clearly convalescing. In that case wait till the acute symptoms are over. Healthy appendices should be left alone. The above counsel does not contraindicate rest, stomach lavage or the withholding of food, and of which measures can be employed as needed with or without operation. Lastly, life is not the only question; time and after-conditions are also important. Adhesions may be temporarily life-saving and later deadly. The waiting treatment favors them. After operation the patient is usually up in from ten days to three weeks. The rest treatment takes a much longer period of time.

The Lancet, April 8, 1905.

Esophageal Pouch Successfully Treated by Excision.—A. B. Barrow and J. Cunning report the case of a woman of 55 years, who had had dysphagia for eight years. Later she began to regurgitate but not vomit food. A diagnosis of malignant disease had been made. On examination of the neck no swelling or enlargement of the glands could be detected, but on bilateral pressure over the esophagus just below the level of the cricoid cartilage, a certain amount of gas could be squeezed up into the mouth. On swallowing two or three times gas could again be squeezed up. A medium sized bougie stopped eight inches from the teeth and could be felt to the left of the trachea. A small bougie could be passed into the stomach. A diagnosis of esophageal pouch was made and an operation done. On exposure of the gullet there was seen lying to the left of it and behind it a white fibrous-coated pouch and one and a half inches long with the bougie in it. On tracing the pouch upwards its neck was discovered to be in the lowest part of the posterior wall of the pharynx. The bougie was now removed, and the fibrous coat of the neck of the pouch was divided and turned back as a cuff. The mucous membrane was then ligatured and cut through and the fibrous coat was stitched up over it. A few stitches were put in to bring the muscular coat together over the site of the neck of the pouch. The patient was fed by nutrient enemata for seven days and was then able to swallow milk. At the end of a fortnight she was discharged with the wound healed, and was able to swallow any kind of food.

Purpura as a Late Complication in a Case of Scarlet Fever.—The patient of J. W. Miller, a boy of 4 years, ran through the usual scarlet fever course—the temperature not subsiding to normal until some two weeks after the initial symptoms. Three days later it began to rise, and next day enlargement of the glands on both sides of the neck was noted, with much tenderness on pressure. About a week later hemorrhage was noticed about the tissues of the left eye, and bleeding occurred from both nares. Gradually purpuric areas appeared over various portions of the body. Uremia supervened and the patient died on the twenty-eighth day from the onset of the original disease.

British Medical Journal, April 8, 1905.

Obliterative Arteritis.—E. Michels and F. Parkes Weber described about two years ago two cases of obliterative arteritis in young men, leading to gangrene of the extremities. They were both poor East End London Jews. The patient whose case they now report belongs to the same class and nationality. He is a cigarette maker, 39 years of age. The trouble began when he was 23 years old, with pain in the right extremity. It came on after he had walked for a few minutes, and was a kind of "intermittent claudication." The foot was quite red at that time. On account of his sufferings, the right lower extremity was amputated below the knee joint. Later on, he began to suffer with the left extremity in the same way he had suffered with the right. He had been accustomed to smoke at least ten cigarettes a day, and had also taken a great deal of strong tea. Examination revealed nothing abnormal in the urine. The nervous system showed no signs of disease. The arteries and nutrition of the upper extremities seemed to be natural. Pulsation was hardly, if at all, perceptible in the left popliteal artery. First of all, the left big toe was removed on account of gangrene. The wound did not heal properly, and intolerable pain in the foot continued, so that amputation was again practised, this time below the knee. There was scarcely any bleeding from the cut vessels, and the lumen of the popliteal artery was found to be completely obliterated at the site of amputation. Recovery was uneventful. Examination of the popliteal artery showed its lumen to be obliterated by fairly dense connective tissue containing a great number of newly-formed blood-vessels and a certain amount of pigment granules. Part of the connective tissue was probably the result of organization of a thrombus. The condition of the anterior tibial artery was similar to that of the popliteal. The dorsalis pedic artery showed an extreme degree of endarteritis proliferans. The muscle fibers throughout showed complete absence of transverse striation and the presence of very marked fibrillation. There seemed to be an excess of nuclei in some of the connective tissue. The writers believe that in this case there can be practically no doubt that the occlusion of the larger arteries was due to thrombosis. The disease occurs almost exclusively in the male sex. The writers' cases seem to have been free from alcoholism, syphilis, and premature senility. They believe that tobacco might help to induce this affection in predisposed individuals, although it would not do so in most ordinary persons. They think also that it is possible that both poor or unwholesome food and racial factors may play a part in the etiology.

The Lowering of the Body Temperature in Hyperpyrexia by Means of Rapid Evaporation of Water.—Louis Henry describes a scheme which he has improvised for the lowering of body temperature as follows: The patient's bed is covered with some waterproof, over which is placed a sheet of toweling. This toweling, the sides of which are cut in a slant, is braided with jaconet. The patient reclines on the sheet, and if necessary has a warm bottle at his feet. Over the whole of his trunk another piece of toweling is placed in one or two layers, hemmed and bound along its sides with jaconet. A cradle is placed over the bed, to the dome of which is attached a small electric revolving fan surrounded by a wire cage. Affixed to the cradle is a small rose, through which water slowly sprays in fine driplets on to the toweling covering the patient. The fan, revolving more or less rapidly, affects the evaporation of water so that the degree of cold can be regulated to a nicety. After taking the patient's temperature, the electric installation is switched on. A rapid evaporation of moisture lowers the temperature. If there is any surplus of water, it will run down the jaconet drains into a receiver at the foot of the bed. A few large fans in the ward would keep the air pure and cool the atmosphere.

Protective Power of Vaccination.—H. J. Neilson reports the case of a mother, aged 37 years, who was attacked with smallpox, and was taken to the hospital with her seven-months-old baby, which she was nursing. The infant had been successfully vaccinated fourteen days previously. The baby was not weaned, but was nursed by the mother throughout her illness (confluent smallpox) and was handled daily by about fifty other patients in various stages of smallpox. The child left the hospital in perfect health.

A Rare Form of Dislocation of the Ankle.—Thomas Eastes reports this case. The patient, in descending some stone steps, missed his footing and twisted his foot out under him as he fell. When the writer saw him he was in great pain and was lying flat on his back. The patella of each knee looked straight upward. The right foot was pointing straight upward, but the left was lying transverse and flat on its outer side, dislocated at the ankle joint by being rotated exactly a right angle outward on its vertical axis. It was neither too far forward or backward, but simply rotated. The tibia was unbroken, and the internal malleolus projected considerably. The anterior surface of the lower end of the tibia was still more prominent. The fibula was broken by an oblique fracture extending downward and inward in its middle third. The external malleolus was twisted outward and backward, with the outer side of the astragalus so that the two malleoli were separated behind by only three-quarters of a circle in front. The astragalus, though still in contact with the articular surface of the tibia, was at a right angle to its normal position. The tendo Achillis and the heel looked practically normal. The inner side of the tibia was very prominent and the skin was stretched over it like a corkscrew. The two most striking features were the peculiar transverse position of the foot and the strange appearance of the anterior face of the lower end of the tibia. The foot was not at all averted or inverted on its longitudinal axis, but rotated a quarter of a circle on its vertical axis. Under an anesthetic, the foot was replaced with slight extension and internal rotation. It went into its normal position with a snap.

Berliner klinische Wochenschrift, March 27, 1905.

The Nature of Malignant Growths.—Hansemann, although he says he has no fundamental objection to the parasitic theory, after analyzing all the arguments advanced by the advocates of this view, comes to the conclusion that they have not proved their case, and that it is not likely that they ever will. No unimpeachable instances of inoculation from man to animals have ever been recorded, and the cases in which a positive result has been alleged by transference from one animal to another of the same species are simply transplantations and not inocula-

tions. The theories in which heredity and trauma play the important rôle are likewise not to be credited, for careful inquiry into cases detailed as evidence in favor of these standpoints usually reveals fallacies in the line of reasoning. The apparent increase in carcinoma is due to the fact that a greater number of people nowadays live to the age at which malignant disease occurs, and to better education of physicians in making diagnoses. The figures of de Bovis, for example, show that if the statistics are analyzed it will be found that the number of external carcinomata, *i.e.* those of the skin, breast, and uterus, has not grown, the increase being entirely in the internal growths only accessible to the improved diagnostic methods of today. The tendency to disseminate among the laity alarmist notions as to a great increase in the occurrence of malignant disease, and especially claims as to its infectious origin, are extremely ill-advised and tend to render the lot of the unfortunate patient still more wretched by causing him to be regarded as a source of danger to others. The author's own view is a very generalized one, which assumes that the causation of malignant tumors depends on the interrelation between irritation and irritability, using the terms in the broad sense of Virchow, which underlies all pathological processes. Some persons are by nature more susceptible to irritation than others, and in these some slight irritation may be enough to incite tumor formation. The probability is that it is wrong to attempt to find a single etiological factor for all types of tumors, and it is possible that we shall find separate causes for the different groups.

Münchener medizinische Wochenschrift, March 28, 1905.

The Alternating and Pseudoalternating Pulse.—Volhard analyzes the cardiograms and pulse tracings of two cases of each of these conditions, and arrives at the following conclusions. True cardiac alternation can occur, consisting of rhythmic alternations of strong and weak systoles of the auricles as well as of the ventricles. A disorder of rhythm is to be noted only at the pulse and not at the heart, the smaller pulse wave being retarded. This retardation is not the result of changes in conductivity, but is due to the less active contraction of the smaller systole and the higher pressure in the aorta. The occurrence of an extra systole may reinforce the alternation to such a degree that intermittence of the smaller pulse may be caused. There is only one form of alternating pulse, that in which there is a retarded small wave. If the latter appears at the correct interval or even ahead of time the condition is one of pseudoalternation, simulated by extra systoles. The retardation in true alternation destroys the regularity and simulates arythemia, while in pseudoalternation the irregularity is compensated and regularity is simulated.

Renal Injuries.—Habs reports four cases of subcutaneous rupture of the kidneys. Three forms of the injury are to be recognized. (1) Superficial contusions of the renal substances. (2) Deep tears and destruction of tissue reaching to the renal pelvis. (3) Tearing of the renal vessels or ureter, or of the entire hilus. Three of the author's cases belonged in the second class. One case recovered without operation; both the others were nephrectomized to check the hemorrhage. One of these patients died of peritonitis on the tenth day in consequence of the sloughing of the colon, the other recovered. The fourth case was remarkable in that no blood or albumen at any time appeared in the urine, although the persistent oliguria, pain, etc., left no doubt that the injury belonged in the first class. The patient recovered under non-operative treatment. The treatment comprises morphine, rest, and lowering of the head for shock, and ice locally, and injections of ergotin or gelatin for the bleeding. Cardiac stimulants must be avoided. Küster has shown that nephrectomy, long regarded as the proper measure for stopping the loss of blood, is better replaced by tamponade and suture of the damaged organ.

Deutsche medizinische Wochenschrift, March 16 and 23, 1905.

Quinine Sulphate as Oxytocic.—Backer says that inasmuch as we are still without any absolutely certain means of insuring sterility of the hands, and as practitioners must constantly come in contact with extremely infectious material, any method which permits the conduct of labor with a minimum of personal manipulation of the patient deserves recognition. The use of quinine as an oxytocic he says has not yet received the degree of consideration it merits, and he recounts the very gratifying results he has obtained by its employment in many cases which would otherwise have required instrumental delivery. Although its effect is not absolutely to be depended on, it is effectual in so many instances that its routine use in suitable cases is to be recommended. Its action is particularly marked in strengthening already existing pains, and it is superior to ergot preparations in that it calls forth strong contractions of the normal sort, with intervals of repose. Large doses are required, best given in amounts of 0.5 g. repeated two or three times at short intervals. The first dose is often ineffectual, while the second or third may be promptly followed by strong contractions. No disagreeable symptoms have attended its use in this way. The manner in which the drug affects the uterus is still undetermined, but it seems likely that its action is a central one.

Aceton Celloidin Imbedding.—Scholtz describes a technique by means of which it is possible to obtain satisfactory celloidin blocks of tissue for sectioning within twenty-four hours. The material, which must not exceed 3 mm. in thickness, is placed directly in pure aceton, either in the fresh state or after preliminary fixation in formalin or alcohol. The receptacle is kept in a warm place, and at the end of one-half to one hour the specimens will be sufficiently dehydrated. It is not absolutely necessary to change the fluid during this time. They are then placed in thin celloidin, curettings, etc., being first washed off with alcohol and ether to remove small remnants of the aceton which might otherwise remain in the fissures of the specimen. The celloidin is kept at a temperature of 37-40° C. for four to five hours, at the end of which time thick celloidin is added, and in two or three hours more they are put into just enough thick celloidin to cover them. Hardening is hastened by placing the specimens under a glass cover with an open vessel of chloroform. After twelve to fourteen hours the blocks are placed for a few hours in dilute alcohol to finish the hardening, and are then ready for cutting. An essential for success is to use only the best anhydrous celloidin and to employ only absolute alcohol in making the solutions. One advantage of the method is that it permits the making of sections of fatty tissues hardened in Flemming's solution, without dissolving the fat.

Clinical Observations and Experiences with Pneumococcus Serum in Croupous Pneumonia.—Knauth says that the results obtained in the eye department of the Würtzburg University Clinic by means of pneumococcus serum in the treatment of corneal ulcers due to the pneumococcus, were so very encouraging that he extended its use to seven cases of lobal pneumonia. The serum employed was a polyvalent one, obtained from different animals by immunizing them with different varieties of the organism. In no case were any disagreeable effects noted, the site of injection showed no reaction, and no inflammatory or erysipelatous redness resulted. No skin rashes or nephritis were observed, and the albuminuria present was purely febrile, as it subsided as soon as the temperature came down. Shortly after the injection the pulse, respiration, and temperature, the character of the expectoration, and especially the general subjective condition, greatly improved. Patients who had been groaning and complaining, or apathetic, appeared transformed, conversed with their neighbors and took an interest in their surroundings. A sudden critical drop in temperature was observed but once, ordinarily the patients perspired but little, the fever diminished gradually, and convalescence ran a normal course. In a case in which the injection was given early it appeared as if the attack were aborted, but the author admits that this may have been a mere coincidence.

A Contribution to the Question of Pressure Narcosis.—Engelken reports a number of improvements made in his anesthetizing chamber for intrathoracic operations. It now consists of a hexagonal cabinet constructed of iron, with glass sides, and sufficiently large to contain the anesthetist and the head of the patient introduced through an opening level with the top of the operating table. By suitable pumps the atmospheric pressure within the cabinet can be raised to any desired degree, and provision is also made for abstracting the free chloroform fumes and admitting fresh air. The apparatus has been used in four operations, three upon the same patient for a metastatic tumor of the lung, and the other for empyema. In each instance the anesthesia was easily maintained without inconvenience to either the patient or anesthetist, and opening of the pleural cavity was not followed by collapse of the lung. Whether this principle is preferable to that of enclosing the patient's body and operator with his assistants in a larger cabinet in which negative pressure exists, can be determined only by further comparisons of the two methods.

French and Italian Journals.

Meningitis with Insidious Evolution a Cause of Mental Alienation.—L. Marchand demonstrates that meningitis of insidious type gives rise to mental troubles. It is difficult to tell just the nature of the lesions. He concludes that the same kind of cerebral lesion can provoke different mental syndromes. The nature, the intensity, the localization, and the extent of the lesion, and the age at which the disease occurs all have to be taken into account. There is a type of insidious meningitis which gives rise in the adult to mental troubles only. In the child it often provokes epilepsy. There are two special types of this form of men-

ingitis, with numerous intermediary varieties. In one type the meningeal lesion is of such a kind that the inflammation is evident; in the other the meningeal lesion is arrested in its evolution. These forms of meningitis bring about alterations in the superficial layer of the cortex, without degeneration in the pyramidal fibers or in the olivary body. To the first type of meningitis there corresponds a dementia with progressive but slow course; in the meningitis which is arrested in its evolution the mental syndromes remain stationary during many years. It is difficult to distinguish between the nature of the forms of meningitis which are arrested in their evolution and those which have a slow evolution.—*Gazette des Hôpitaux Civils et Militaires,* April 6, 1905.

Ascites in a Woman 22 Years of Age.—Chauffard describes the case of a woman 22 years of age whose illness began with a feeling of fatigue. The personal history was negative. The appetite failed, emaciation progressed, and constipation developed. The menses at first became more abundant, but were finally completely suppressed. The patient's mother, two years before, had been operated on for uterine fibroma. A tumor was detected in the right iliac fossa of the patient, and the physician consulted diagnosed the condition as that of pregnancy. At this time the presence of ascites was detected. Pleural effusion, which was also noted, increased until a thoracentesis on the right side was performed. Eight and one-half liters of deep yellow liquid were drawn off after a puncture was made in the ascitic region. The cervix was firm, and over the body of the uterus were felt two bosselated tumors, separated by a deep groove. Fever developed, followed by phlebitis, and the patient died ten months after the beginning of the illness. Autopsy revealed two large tumors, one developing from each ovary. There were no adhesions. The structure of the tumors was diverse. In places was seen the tissue of fasiculated sarcoma, or myxoid sarcoma, while in other parts the growth was distinctly epitheliomatous. Metastases were observed. The writer states that ascites is observed in all cases of malignant growths of the ovaries. Cancer cells were noted in the pleural liquid which was examined. It is difficult to say if an operation in the early stages of the disease would have been successful. Cancer of the ovary has always a grave prognosis, especially in a young woman.—*Journal des Praticiens,* March 25, 1905.

Cerebrospinal Meningitis with Relapses.—Letulle and Lemierre report a case of cerebrospinal meningitis due to the organism of Weichselbaum, in which there is a history of relapses. The first attack, which was serious, lasted twenty days, at the end of which defervescence took place brusquely. For a month it seemed as if the patient had entirely recovered; but suddenly the symptoms of meningitis reappeared, accompanied by severe general symptoms. Five days later the course of the disease followed the same order as in the first attack. Twelve days later there was a second relapse, which ended in definite recovery. However, the patient still has stiffness and trouble in walking. The cephalorhachidian liquid which was withdrawn at the beginning of each attack was distinctly purulent. At the time of recovery in each instance it had become serofibrinous. The presence of the meningococcus was determined in the cephalorhachidian liquid during the first two attacks. During the second relapse it could not be found. The organism did not prove virulent for a mouse, into the peritoneum of which it was injected.—*Le Bulletin Medical,* March 15, 1905.

Tumor of the Cecum; Transplantation of the Ileum into the Transverse Colon; Recovery.—Le Bec had under his care a patient afflicted with chronic obstruction due to a tumor of the cecum with multiple adhesions. He first made an iliac anus. The small intestine being found, he transplanted the ileum, after sectioning it, into the transverse colon. The transplantation was made into a longitudinal incision of the colon. Two sutures passed into the small intestine were afterwards passed into the colon. In drawing tight the ends of the sutures, so placed, the operator invaginated the small intestine into the colon, and terminated the operation by placing a triple row of seroserous sutures.—*La Presse Medicale,* March 29, 1905.

Mitosis in the Corpora Lutea.—Giovanni Paladino has made careful researches as to the formation of the corpora lutea in the bitch. He believes that great errors have been made in regarding it as a new formation of epithelial origin, and as to its function. He has shown that it is a new formation of connective tissue. His conclusions are as follows: (1) Mitosis is a form of multiplication largely represented in the formation of the corpora lutea, as well in the lutein cells as in the vessels, and can be demonstrated as well in the preparatory stage as in the fully formed follicle. (2) The place of genesis of the corpus luteum is the theca folliculi, with participation to differing degrees of the internal and external layers, at the expense of the elements near by as well as those which come by migration. (3) The nature of the corpus luteum is undoubtedly connective tissue. (4) Its significance is so formulated by him, that it serves at first to prepare and produce the rupture of the follicle, and afterwards to produce repair and cicatrization of the ruptured sac.—*Archivio di Ostetricia e Ginecologia,* February, 1905.

Tabes in Youth.—Augusto Clannelli reports a case of tabes not of syphilitic origin, in a young girl. Such cases have been rarely reported, there being records of only forty cases, 30 of which, when examined, prove to be other forms of tabes, only 10 being pure non-syphilitic tabes of youth. The patient was a girl of 17, who had no specific history; after a sea bath, taken at the time of menstruation, she began to have lancinating pains in the limbs, with cephalalgia and hemicrania. At 22 she had Argyll-Robertson pupil and Westphal's symptom. She had hyperesthesia of the thorax and along the inner border of the arm, and abolition of the knee and Achilles tendon reflexes. Pure tabes in children is very rare, and most cases have a syphilitic taint. This case was improved by treatment. It is certain that adult cases are also sometimes improved under treatment, hence this need not throw any shadow on the diagnosis of this case.—*La Riforma Medica,* March 25, 1905.

Scapular Hypophonesis and the Sign of the Scapula.—Signorelli considers the scapula as a large osseous plexi-meter, applied against the posterior superior part of the thorax. The sound that it gives on percussion is not entirely due to the osseous vibrations, but also to the vibration of the adjacent parts, and so adjacent is one-half of the thorax that it may be said that the scapular sound will change with the changes that go on in the thorax behind it. It also is affected by the conditions present in the entire thorax. The author has studied systematically the changes which take place in the scapular resonance, in healthy as well as diseased persons, having pulmonary lesions, and gives us his conclusions. Whenever on percussion at the median extremity of the spine of the scapula there is a hyperresonance, and this cannot be attributed to an assymmetrical position of the scapula, or a deformity of the spine, it indicates alterations of the thoracic organs in the region covered by the scapula. One especial form of hypophonesis is that produced by effusion into the pleural sac, reaching up to the angle of the scapula. The author calls this hypophonesis the scapular sign of pleural effusion, because only in this is it obtained, and it is absent in the hepatization of pneumonia, when limited to the lower lobe of the lung.—*La Riforma Medica,* March 25, 1905.

Criminal Abortion.—Puppe in the course of his medico-legal work had occasion to investigate twenty-eight cases of criminal abortion in Berlin and northern Prussia. In sixteen of the cases the result was obtained by mechanical means, of which two comprised puncture of the membranes, and fourteen the injection of fluids into the genitals. In many of the cases, in addition to the manipulations, the internal administration of vegetable infusions, decoctions of unroasted coffee beans, hot baths, and applications to the genitals, etc., were resorted to as adjuvants. An interesting point is that the operative procedure was rarely undertaken with the patient in a horizontal position, but usually the abortionist knelt before the patient, who was seated on the edge of the chair or between two chairs. In this way the cervix becomes more easily accessible and shorter instruments than are usually supposed necessary suffice to enter the uterine cavity.—*Monatschrift f. Geburtshülfe u. Gynäkologie.*

Medicated Ointments in the Nose.—A. W. MacCoy has made a series of observations on the therapeutic value of medicated ointments in certain affections of the nasal chambers, and offers the following conclusions: (1) Notwithstanding our bent of mind towards surgical procedures for the relief of diseases of the nasal chambers, the rational employment of drugs must still occupy our attention. (2) Our constant and persistent use of nasal washes, especially during the winter season in our climate, tends to harmful results. (3) By the employment of curative medicaments in the form of soft ointments in the nasal chambers, we can avoid certain risks following the use of washes, etc., and at the same time further the advancement of our patients toward a speedier cure. (4) The availability, convenience, and adaptability of medicated unguents in the therapeutics of the nasal chambers appeal in a rational manner for their employment. (5) Ointments prescribed should be dispensed in collapsible tin tubes as a protection from contamination, and because this form of dispensing renders them most convenient for use at all times and in all places.—*The Laryngoscope.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 23, 1905.

Dr. CHAS. F. ADAMS IN THE CHAIR.

Adenocarcinoma of the Uterus.—Dr. [illegible] presented this specimen which represented an early stage of adenocarcinoma of the uterus, and, historically, belonged to a subject of recent date. It was removed from a patient, 57 years of age, who had always been regular in menstruation. She had given birth to fourteen children normally and enjoyed perfect health until two years ago, when menorrhagia set in, which was at first controlled by the usual methods, but after a few months recurred. Two months ago it became uncontrollable. When he first saw the patient he found a stout lady with some myocardial degeneration. The uterus was enlarged and somewhat hard. Just within the cervix he could feel a little ovoid round hard mass. He said there was an appearance or condition about these cases which impressed one at once with their malignancy, and he could not tell why. In the early stage of these growths they suggested nothing more than what was found in early fibroids, yet the general condition, appearance and symptoms were such that one who had much experience with these cases could almost instinctively suspect the condition. The doctor who referred the case to him objected to the diagnosis of malignancy and insisted upon curettage being carried out. Dr. Sturmdorf refused and said that unless permitted to do a hysterectomy he would withdraw from the case. At last he obtained the consent and did a hysterectomy. He sent specimens of the tumor to three different laboratories of this city and the diagnosis from one was simple cystic adenoma, from the other two adenocarcinoma of the uterus. A cystic adenoma of the uterus was almost known. At present it looked more like a simple fibroid. There was a distinct demarcation line, and some of the cavities were filled with a colloid material. In these cases he said one could not be too careful in diagnosis or too radical in treatment.

Essential Metrorrhagia; Hysterectomy.—Dr. Sturmdorf presented this specimen which in a way was a counterpart of the first one presented. The two together represented one of the many obscure symptoms, namely irregular bleedings in the early and late stages of menstruation. In women from 17 to 30 years old, but more often in the earlier stages, one could not account for the severe conditions of uterine bleeding, which, in some conditions, appear regularly, and in others appear irregularly. There could not be found any heart, kidney, circulatory, or other trouble to account for it, and no anemia except what would naturally be caused by the hemorrhages. These women might go from doctor to doctor, and finally sone one would be compelled to do a hysterectomy. This patient was a single woman, 28 years old, and she had been bleeding for seventeen years. Her menses started early. She did not come from a family of bleeders. He saw her first ten years ago. She had been curetted about 30 times by men who knew how to curette. At last the amount of hemoglobin got below 30. When the uterus was examined nothing wrong could be made out, so far as the naked eye was concerned. Dr. Sturmdorf said that in a recent study of fibroid tumors he brought out certain facts regarding metrorrhagia occurring in old people. Some had varicose veins in the broad ligament, and degenerated myometrium. He said he had demonstrated some years ago that an unimpregnated uterus presented rhythmical contractions, same as an impregnated one, and that this contraction of the uterine muscle had much to do with the return circulation in the broad ligament. The studies of certain men had shown that in some cases there was no degeneration in the uterus after the menopause, especially in old women who had metrorrhagia, without some pathological changes; yet any muscular degeneration might represent muscular insufficiency, and this had something to do with the metrorrhagic condition found in these cases. Dr. Sturmdorf said he could not tell why these women bled.

Displaced Pyonephrotic Kidney; Nephrectomy.—Dr. Sturmdorf also presented this specimen. It was a mass of a pyonephrotic kidney with a calculus. The patient was a woman, 28 years old, who complained of pyuria. She never had had any pain. This pyuria began three years ago. She first passed pure blood and then pus. All that could be felt was a semifluctuating mass in the right pelvis; it could be felt over the right vaginal fornix. The cystoscope demonstrated the escape of pure pus from the right ureter. No lesion of the bladder could be seen. After cutting down and severing the agglutinated intestines he found a large retroperitoneal mass; he therefore closed the laparotomy wound and went down extraperitoneally and dug out the kidney that he presented. It was riddled with abscesses. He left the capsule behind, and the woman made a rapid recovery. The peculiar anomaly about it was the existence of two pelves. The kidney was displaced. Nature had tried to cure this kidney by fixing it. Some of these kidneys were displaced congenitally. In this case there was a pyonephrosis, or a calculus blocking one of the pelves; the other pelvis was free. Dr. Sturmdorf said it was not usually known that displaced kidneys were subjected to the same diseases that non-displaced kidneys were.

Dr. EGBERT H. GRANDIN, referring to the first specimen presented, said there was no doubt that adenocarcinoma of the uterus was relatively common, and yet they were not able to make a diagnosis as quickly as Dr. Sturmdorf did without resorting to curettage. As a rule it seemed to him wise to curette these cases and submit the scrapings to at least two pathologists before resorting to hysterectomy, the only operation to be done in these cases.

With regard to the second specimen presented he said the main reason for his attending the meeting was to learn what Dr. Sturmdorf meant by "essential" metrorrhagia. These cases must be of extreme rarity. He said he had been called upon to operate for uncontrollable metrorrhagia, but he confessed that he had never seen a uterus removed for such a condition that did not show some pathological change, or cause for the bleeding. Five or six years ago, he said, he presented to the Obstetrical Society a uterus of the same type as that just presented; this woman had been curetted by competent men, and notwithstanding this she reached an almost exsanguinated condition. He again curetted her, and then told his assistant that the only thing to do was a hysterectomy, which he did per vaginam. Opening the uterus he found a small nodule, exceedingly vascular, at one horn where the curette could not reach.

With regard to the third specimen presented, he said he had met with some instances. At times no diagnosis of kidney lesion had been made prior to operation, but only during operation. In one case he found the right broad ligament cystic, and continuous, and adherent to another mass. After attending to the broad ligament he removed the mass extraperitoneally, completing the operation through the median incision.

Dr. BROOKS H. WELLS had removed several uteri for metrorrhagia, but always had been able to find some pathological change to account for the bleeding.

Dr. Sturmdorf said that the simple fact of curetting the growth would produce added injury. In the case reported the scrapings would undoubtedly have been normal endometrium. He wanted to bring out how little one could rely upon the diagnosis made by prominent pathologists, and how little help they would have been in diagnosing the condition found in his patient. If deep scrapings had been taken he said it would have been very difficult to differentiate a carcinomatous from normal glandular arrangement. It was the clinical course of the tumor that differentiated it from benign growths. It should be differentiated by the presence of the carcinomatous cells, the typical arrange-

ment of the stroma; when these conditions appeared then one could be absolutely sure of the diagnosis of carcinoma. In the majority of the cases of "essential" metrorrhagia (Martin's classification), there was to be found some pathological substrata; in some cases this pathological substrata could not be found.

Vaginal Hysterectomy for Chronic Imflammatory Conditions of the Pelvic Organs.—Dr. Herman J. Boldt presented these eleven specimens of uteri, removed from patients who had been treated for several years without being relieved of their symptoms. In all instances the myometrium was increased and resembled the condition which had usually been termed fibroid degeneration. The condition was one of chronic metritis. The endometrium likewise showed inflammatory changes. The adnexa in some instances showed very serious pathological changes. He said it was a very serious matter to be confronted with a question of such grave importance as the removal of the pelvic organs for non-malignant disease, one that should in each instance be most carefully considered. If there was any method of treatment that offered any hope of relief without resorting to such radical procedure, he believed that it should first be tried. In the instances in which the specimens were presented every conceivable plan of treatment had been used from two to five years without success. In all cases the pelvic pains were unbearable and dyspareunia was so intense that coitus caused the most excruciating suffering. He said that it had been one year since the last of these patients had been operated upon, and in all instances the former distressing symptoms had been relieved. The ages of the patients varied from 32 to 43 years. They were all multiparœ, and during their last confinements were said to have had blood poisoning. The symptoms of the forced menopause were present in a more or less marked degree after operation for from one to three years. It was maintained that in such cases the operation was not only justifiable, but that it was strongly indicated. He presented one specimen which showed complete obliteration of the cervical canal, and one centimeter from the uterine cavity, the myometrium had another small cavity of glandular lining. If a myofibroma developed in such a uterus it would be of the type known as adenomyoma, and in such instances we might have a primary carcinomatous degeneration of the neoplasm. The cause of the obliteration of the cervical canal in this instance was ascribed to repeated curettings and local treatments with caustics. The symptoms for which the operation was performed was constant pelvic pain, which was due to salpingo oorphoritis. Since the operation the patient had been free from pain. He also showed a myofibromatous uterus removed per vaginam because of pelvic pain and menorrhagia which could not be controlled by other methods of treatment. Also a specimen of carcinoma of the portio vaginalis uterus removed by vaginal hysterectomy. In this instance a high amputation of the cervix would have in all probability been sufficient, yet preference was given to the radical operation because of the age of the patient, 46 years, besides it was uncertain whether an independent carcinomatous nodule might not have been in the body of the uterus. Another specimen was a carcinoma of the uterus proper, removed by vaginal hysterectomy. The patient, who was 42 years old, had slight bleeding every time after intercourse; there were no other symptoms present. Another specimen was that of diffuse adenocarcinoma of the body of the uterus. The woman had been frequently curetted because of atypical bleeding during the previous three years, but the scrapings had previously shown only an adenomatous endometritis. Still another specimen showed circumscribed carcinoma of the body of the uterus. A vaginal hysterectomy was done and the patient made a good recovery. There was also a specimen of bilateral ovarian carcinomatous tumors which occurred in a patient 25 years old. She said that she had been feeling well until two weeks previous to the time of consultation when she began to have pain in the right lower abdomen, and a swelling manifested itself which rapidly increased in size. There was ascites, which with the nodular feeling on the surface of the tumor, and the rapid growth of the neoplasm indicated the presence of malignant disease. The operation had been performed in the morning of the day upon which the speaker presented the specimen. The ascitic fluid was bloody, and numerous metastases were present. The right broad ligament was removed, and some pelvic glands on the right side, as well as several metastases in the omentum. After having removed these it was thought possible to remove a metastatic nodule between the bladder and the cervix, but this being found impossible the uterus was extirpated. A large tumor, probably also malignant, in the lower part of the sigmoid at the junction with the rectum, necessitated resection of the bowel. The anastomosis was made with sutures and thus far the patient seemed to be doing well.

Dr. Egbert H. Grandin did not believe many men would favor operating in these cases unless forced to do so. Columbus Hospital seemed to be quite prolific of the type of cases Dr. Boldt referred to, and when operation was decided upon he did not do a partial operation but a total hysterectomy.

Dr. Robert T. Morris asked Dr. Boldt if he had ever performed hysterectomy for endometritis due to the colon bacillus. These cases at times were exceedingly intractable and recurrences were frequent.

Dr. Boldt replied that he had not had an opportunity of seeing such a case.

Dr. Brooks H. Wells thought the second cavity might have been congenital and due possibly to the failure of the duct of Müller to unite. He said he had seen several cases of double uteri.

Dr. Boldt, in conclusion, said it was not impossible to diagnose carcinoma from ordinary inflammatory conditions of the endometrium, as had been claimed by some. He would not care to resort to radical procedures unless the diagnosis was firmly established, and this could always be made by examination of the scrapings; if carcinoma was present characteristic changes took place in the endometrium which enabled one to make a positive diagnosis.

Morbid Processes in the Right Abdominal and Pelvic Regions of the Female, and their Differentiation.—Dr. J. A. Schmitt read this, the paper of the evening. He considered only those abdominal and pelvic diseases which might be mistaken for one another, and he divided them, for convenience sake, into acute and chronic, although any sharp distinction could not be drawn between them. When a woman was attacked by pain in the right inguinal region, fever, vomiting, etc., it might point to an appendicitis, an ascending pelvic peritonitis or cellulitis, or an ileocolic invagination, or calculus through or impacted in the ureter. Still these conditions differed sufficiently in their history and symptoms to allow of an accurate diagnosis. An ascending pelvic peritonitis might be mistaken for an abdominal exudate due to appendicitis, but only on superficial examination, because the history would point to a gonorrheal or puerperal infection. The exudate in the inguinal region would be found to be continuous with that in the small pelvis, and a thickened tube or ovary could be usually found on the right side of the uterus, or both sides might be diseased. Much more difficult was the differentiation from inflammatory residues which had remained in the right inguinal region after the inflammatory products in the pelvis had been absorbed. We thus occasionally found inflammatory cysts in the lower right abdominal region that had been rounded by the dragging and rolling movements of the intestines. They were adherent to their surroundings, and therefore immovable and only slightly tender. They might be taken for a cystic appendix or for an ovarian cyst, though the latter was movable and connected to the uterus by a palpable pedicle. Tuberculous peritonitis was apt to produce similar cysts, containing

serum or pus. Whenever we met cysts of obscure origin in the right abdominal and inguinal region we should seek for further signs of tuberculosis, as lard swellings, as to a rolled up and retracted omentum which usually lay in the epigastrium, as an oblong or square plate-like indurated mass. Intestinal disturbances, referable to the colon, atrophy of the walls of the viscus, stercoral ulcers, local tympanites of the ascending colon, and irritation of the adjacent peritoneum, were conditions which occurred more frequently than we were inclined to believe. They were confounded with slight attacks of appendicitis, from which they were difficult to differentiate. A retrococcal exudate started in intimate relation with the cecum and colon, it involved the same, and made the impression of a columnar mass upon which the soft intestine rested. The exudation which had become isolated might rest on the iliac fossa, but its shape was more flat, expanded, and irregular. The history pointed in the one case to intestinal, and, in the other, to pelvic derangement. Those cases were of great interest in which the patient, after a sudden and acute attack of pain in the right lower abdominal region, passed into a state of collapse. Here we might have perforation of the appendix, acute intestinal obstruction, rupture of a tubal pregnancy, or of a pus sac, or strangulation of an ovarian cyst. The history sometimes assisted us, but very often it was unsatisfactory. All diseases in which the abdominal cavity was suddenly flooded with infectious material presented identical symptoms. We had a rapid, weak, and irregular pulse, clammy perspiration, sunken eyes, yellowish conjunctiva, cold extremities, rapid and superficial respiration, and frequently subnormal temperature. In strangulation of an ovarian cyst or bursting of a pelvic abscess we could always detect a tumor or infiltration into the pelvis with local tenderness. Even though the ovarian cyst had encroached upon the right inguinal region, its connection with the pelvis could always be ascertained. In a perforating appendicitis such a massive exudation did not develop in so short a time nor had it such a regular rounded form. When the uterus was freely movable, and the pelvis free from inflammatory swelling or growths, we were justified in considering the abdomen as the seat of the disease. In perforating appendicitis the pain spread rapidly over the entire abdomen, while in acute intestinal strangulation it remained severe and constant at the same point. Incessant vomiting, absolute constipation, excessive tympanites with local pain and tenderness were the chief symptoms of acute intestinal strangulation. The collapse in the beginning was not so marked. Some of the discriminating points of extrauterine pregnancy were the deadly pallor of the face, the blue lips, repeated attacks of syncope, and dimness of vision. The patient takes a deep breath now and then; she gasps for air. The dyspnea in the other conditions was different. The original agonizing pain subsided and the patient complained of heaviness and fullness in the pelvis. The mental faculties remain clear, while in resorption of infectious material the patient became apathetic. The discovery of fluid blood in Douglas' pouch was in most cases impossible. In acute rupture with dangerous internal hemorrhage German gynecologists advised prompt surgical interference; in tubal abortion with slow and gradual loss of blood and the formation of a retrouterine hematocele, they advocated expectant treatment. The writer thought that in many instances such a standpoint was fallacious, because hemorrhages after acute rupture might also occur gradually and give rise to bulging of the posterior vaginal vault. A serofibrinous pelviperitonitis with a retrouterine hematocele might develop rapidly, again tubal abortion might be followed by a dangerous loss of blood or the contact of the tube and abdominal cavity might become infected, and even without infection it might be several months before absorption of the blood could be accomplished. The appendix might become involved with the pelvic viscera in three ways: (1) The adnexa might be the primary seat of inflammatory changes, the appendix being passively involved and bound by adhesions to the surrounding parts. Inflammatory action was principally manifested by thickening of the peritoneum and the tubal wall. (2) The appendix might be primarily involved; the changes in the adnexa might be of secondary nature. (3) In the course of a chronic salpingoovaritis with pelvoperitonitis a genuine appendicitis might develop. He said that primary affections of the uterine adnexa could usually be recognized. Fortunately, if there might be some difficulty in differentiating these conidtions, the one plan of treatment was applicable to all, removal of the diseased organs by operation. He considered tumors of the kidney and ovary as more important though the possibility of the occurrence of tumors of all kinds should be borne in mind. It was not difficult to differentiate between these two kinds of tumors; if any doubt existed the cystoscope could be relied upon to settle the question. He described how these conditions could be distinguished from one another by palpation. To eliminate errors in diagnosis the *x*-ray and ureteral catheterization had been advised. One of the most interesting points in differential diagnosis referred to inguinal pains. Where the line connecting the anterior spine crossed the external borders of the recti muscles, tenderness and pain were often experienced by women, they were of rarer occurrence on the left than on the right side. This pain might be very obstinate and seem to justify operation on ovaries and appendices. Errors could be made in this way, but they could as well be made by pronouncing a patient hysterical or neurasthenic, while a chronic appendicitis or ovaritis really existed. He called attention to the diagnostic points in the various pelvic conditions that might give rise to the same class of symptoms as those shown in hysterical conditions.

Dr. Brooks H. Wells told of the difficulties encountered in making a diagnosis. For instance, in appendicitis we were supposed to have a rapid pulse, elevation of temperature and pain, and yet in many cases none of these would be present. Again, rigidity was often given as a sign, but this was not present unless peritonitis developed. The importance of an early diagnosis was dwelt upon. He believed that every case of peritonitis of acute form, unless localized, required an abdominal section. Hysterical conditions with pain were diagnosed quite readily; the pain was apt to be superficial, and if the integument were pinchced it would excite more pain than would deep pressure. In true inflammatory conditions deep pressure would cause pain; in hysterical conditions a steady relaxation of the deep pressure would cause pain.

Dr. Robert T. Morris said that fewer mistakes were made in diagnosis in cases that went to operation than were made by the internist; he doubted if more than 1 per cent. of the cases that went to operation were wrongly diagnosed. Dr. Morris referred to certain instances that had occurred in his experience in which wrong diagnoses had been made. One of the most important signs in cases of abdominal disturbance was spasm of the abdominal muscles. If the kidney was in the appendicular region this spasm would occur. But the history of the presence of a mass there for a long time, and the fact that the organ could be pressed back into position beneath the ribs without difficulty would diagnose the condition; yet this spasm of the abdominal muscles, he said, might mislead one and make one think he was dealing with some acute inflammatory process. In making a differential diagnosis between an acute appendicitis in the pelvis and acute tubal disease this point obtained on palpation became of very great value. In the former there was such a distinct and marked spasm of the abdominal muscles that one could hardly mistake its significance; a corresponding degree of inflammation in the oviducts or ovary would hardly give any such spasm; this difference in the amount of spasm was due to the group of sympathetic ganglia involved in each case. The normal appendix could be palpated in every instance and with perfect ease by following the plan he had already described. If the abdomen was so rigid

that palpation of the organs could not be done it was time then for an operation. Dr. Morris did not favor removing normal appendices when opening the abdomen. In many hundred operations he had only met with cystic appendices twice. The diagnosis in each of these cases was made by palpation.

Dr. Egbert H. Grandin said that it was quite a hazardous thing to make a positive diagnosis of any acute adnexal or appendical affections in the right iliac region, when the two conditions might be combined there; anyway, regardless of the diagnosis, the treatment was operation. As a rule, the things to depend upon were careful history taking and most thorough examinations, particularly rectal, and this would enable one to differentiate adnexal disease from appendicitis, unless the conditions were combined, and this occurred in about two per cent. of the cases. Not necessarily would the appendix be coarsely diseased, but adherent to a diseased tube or ovary. Here the subjective symptoms would be of such a nature that bimanual palpation would be almost impossible and rather unnecessary. If one was dealing with an appendiceal abscess which had ruptured, or with a pyosalpinx, or a rupture of an extrauterine gestation, he said it was not a question of an accurate diagnosis; the only thing to do was to operate. He said he knew of no organ in the body except the appendix that was so apt to lead one astray and he always took the appendix out when it could be done. He had seen cases of pyosalpinx simulate appendicitis. He frequently had found a long appendix down in the pelvis in women. The term "McBurney's point" had led him astray more often than any other in medicine. In women one rarely found pain at this point. It was not so much a question of pain as a question of stating that the condition existed. Where the disease was below the pelvic brim he did not believe that any man who was familiar with diseases of the female sexual organs would make wrong diagnosis; but when the malady was above the pelvic brim then difficulty in diagnosis would occur. An extrauterine pregnancy before or at the time of rupture was not likely to fool a man trained in diagnosing diseases of the female sexual organs. Bimanual examinations, especially per rectum, would reveal the presence or absence of diseased adnexa, etc. In chronic conditions there need be no haste in making the diagnosis. He believed that it was the so-called "cock-sure" surgeon who made the most mistakes in diagnosis.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 27, 1905.

Dr. Henry S. Stearns in the Chair.

A Few More Words Concerning Radium, with Special Reference to the Alpha Rays and to the Emanation.—Dr. Henry G. Piffard said about one year ago he had had the pleasure of making some remarks about radium and that his interest in radium had not ceased because certain problems had presented themselves which he was desirous of solving. The first of these was to see if a more economical use of radium could not be found; in other words, if one could not use some of the lower activities to obtain the same results as now were obtained by the higher activities. There had been some change of belief as to the character of the radium disintegration. Radium was said to give forth three kinds of rays, the alpha, beta, and gamma, and an emanation. The emanation given off was in the form of gas. A later view of Rutherford was that this was an error and that radium gave out only alpha rays and the emanation. The beta and gamma rays were not the result of the disintegration of the radium, but the disintegration of the emanation itself. Dr. Piffard said that he first began the study of radium about two years ago and he took a glass tube of radium to Columbia University and tested it. He tested it first in the tube. It was found that its activity, as indicated by the electrometer, was very slight indeed. He then removed the radium from the tube and found, to his great surprise, that the naked radium was vastly more active than the same radium when in the tube. Physicists claimed that the alpha rays from radium constituted 95 per cent. of the total radiation and also that the alpha rays had but slight penetrating power and would not go through glass or aluminum tubes and would hardly go through certain tissues. But if it was exposed naked, then its activity was increased. He believed the direct use of naked radium was practicable, but certain difficulties were now encountered, such as its cost. If one used the naked radium it was virtually lost to the world. If it was dissolved in water and injected into tissues it again was practically lost to the world. Dr. Piffard said he had never used the naked radium, or radium in solution, except in one or two experimental trials on his own skin. Radium could be painted on discs and then could be made to stick; if the menstruum used would permit the alpha rays to pass through it, then the preparation could be conveniently used in the form of discs or sticks. As a result of his study he found that he could coat various needles with radium and that the radium would stick closely to the rods and that the alpha rays were not confined as in glass tubes. The question next arose how to tell whether the alpha rays were active. Dr. Piffard presented a little rod which had been coated with radium solution by M. H. Lieber, and asked how one was to know that certain effects were due to the alpha rays and not to the beta or gamma rays. The test was an exceedingly easy one. If, for instance, one had a little screen coated with zinc sulphide and placed the needle back of it, and gazed at it in a darkened room, it would be found that it glistened on the surface, and, therefore, he knew that that fluorescence was due, not to the alpha rays, but to the beta or gamma rays. On the other hand, if the needle was held in front of the screen and examined with a lens a sparkle of light would be thrown out on each side of the rod. It had been demonstrated that the beta and gamma rays would not produce these scintillations, but that the alpha rays would. The emanations of radium appeared in the form of a gas. After this gas had been separated for a few days from the original radium it exhibited properties which had been associated with the element helium; this was discovered by Ramsey about one year or more ago. The amount of beta and gamma rays coming from the original radium he said was very slight as compared to the amount of alpha rays. Dr. Piffard asked how we were to recognize these emanations. He said there were various ways of determining their presence. The rays themselves could not be blown around. They were projected from the radium with enormous speed, with a velocity of something like 160,000 miles per second for the beta rays. When emanated they were not diverted from a straight course except by a magnet. These emanations are not only radioactive, but they possessed the power of exciting radioactivity in other bodies near at hand. This induced activity was not a permanent one, but only lasted a few days. The methods of testing the efficiency of radium were simple, and three in number, as follows: (1) The photographic; if one exposed a photographic plate to radium it would darken; the stronger the radium the darker the plate in a given time. (2) The electric method; radium near the electroscope would cause a discharge of it in a given time; if the specimen presented to the electroscope was twice as strong, the discharge would occur in one-half the time; if three times as strong, in one-third the time, etc. (3) The physiological method; if one took a tube of radium and bound it on the arm and left it in place a certain period of time, twenty-four or forty-eight hours, destructive changes, such as severe burns, would be caused. These three methods were not comparable, for the specimen of radium which produced the greatest photographic result would not necessarily produce the greatest physiological result, and *vice versa*. Formerly it was thought necess-

sary to use the strongest preparation possible of radium and use it in as massive quantities as possible, as was procurable. Evidently now there was but little radium and very little of high power. The effect of radium depended upon the activity multiplied by the mass or quantity. He stated that Dr. Abbe had in his possession as much as 150 mg. of 300,000 activity, and he did not believe there was another man in this country who had as much of this activity in his possession that he could call his own. Dr. Piffard here related some of his experiences with the rods coated with radium. One great trouble encountered was that after the rods had been left in morbid growths for twenty-four or forty-eight hours, and then removed, it would be found that their activity was entirely gone and could not be restored. In other words, the tissues soaked out the radium from the rods. Dr. William S. Stone had used a rod in cervicitis, leaving the rod in for twenty-four hours at a time, making five applications in all at a few days interval. Dr. Piffard had just tested that rod and found it to be still active. Here was one instance where the rod had not lost its activity, but in the majority of the cases the rods would lose their activities after being used. If the needles presented could be coated in such a way that any physician could use them without impairing the activity, one readily could see the economy of it. Dr. Piffard followed his opening remarks by a demonstration of fluorescence and radioactivity.

Experiments with Radium Emanations.—Dr. Wendell C. Philips read this paper. He said that at the suggestion of Hugo Lieber a properly constructed tube, by means of which the emanations could be made use of experimentally, had been placed in his hands for experimental work along the lines covered by his work in the field or nose, throat, and ear. He referred to the descriptions of emanations as given in the literature on the subject of radium and radioactivity and quoted Madam Curie's definition of emanations, namely, "the gases present in an enclosure containing a solid salt of radium are radioactive. This radioactivity persists when the gas is drawn off with a tube and collected in a test-tube." It had seemed to him that before commencing experiments upon patients it might be wise to determine whether the emanations possessed any bactericidal power. A pure culture of streptococcus was exposed for a period of two minutes several times during the day and it was found that the bacteria did not lose their activity. Inoculations from the exposed culture grew in new media with the usual speed, and the culture itself showed no effect from the action of the emanations. A culture made from a pure culture was exposed immediatelv after inoculation for the same time, the exposure to the emanations taking place before the newly inoculated media was placed in the incubator, and the culture prospered in the usual way. A mixed culture taken from the ear discharge was in no way affected by exposure to the emanations. The discoverers of radium, as well as various observers, agreed that the activity of the air in the enclosed tube rapidly lost its radioactivity when fresh air had access to the tube; it was always so applied to the part to be treated that the first current, carrying the greatest amount of the radioactive substance, fully bathed the part. An exposure of two minutes was the time usually employed. The treatment was generally repeated daily. One patient, aged 33, who was thus treated, had had the exanthemata, but no ear complications. At the age of 19 syphilis was contracted, which was pronounced cured after three years' treatment. Four years ago the patient had an attack of laryngitis and could not use the voice for five months. Three years ago a discharge from the right ear began and had been fairly continuous. The patient was diagnosed as chronic suppurative otitis media, with a polypoid mass of granulation or polypoid tissue, which filled the whole external auditory canal. After cleansing the canal thoroughly the growth was exposed to the radium emanation for two minutes. After treatment the growth would at first appear red, and after a few seconds it became pale. After thirty days' treatment no definite change could be noted. A second case had complained of excessive discharge from both sides of the nose, with obstructed nasal respiration and pain in the head. Here the nose had been completely cleared of polypoid degeneration and the ethmoidal cells had been thoroughly curetted. Before beginning the radium treatment there was still some discharge, evidently from the ethmoidal cells. The treatments were continued for about six weeks. The patient thought there was some relief after treatment, but there seemed to be no appreciable change, the crusts forming in about the same manner as before the applications were made. Three cases of suppuration of the middle ear with rupture of the drum, in one of which microscopic examination revealed bacilli identical with the Klebs-Löffler were treated, with negative results. He related a case of atrophic rhinitis and ozena, in which he had first removed all crusts from the nasal cavity and, after drying the surfaces, had applied the emanations in both nostrils. There was some improvement, which was probably due to the careful removal of all crusts. When treatment was discontinued the original condition soon returned. Another case of atrophic rhinitis, with a well marked chronic catarrhal otitis media, showed no decided improvement after the use of the emanations. Though this unfavorable report was based on only a few cases, the experiments were carried out with great care as to detail and without bias of any form. The experiments on bacteria would seem to indicate that the emanations would be useless in infectious diseases. He regretted that he had not had opportunity to apply these emanations to cases of benign and malignant tumors of the nose and pharynx, to syphilitic ulcers, or to tuberculous ulcerations, especially faucial.

The Practical Use of Radium.—Dr. Robert Abbe said that in radium we were dealing with a superior force, and whether of great value as a therapeutic agent, remained to be seen. Personally, he believed it to be of value. This force he presented bottled up in a little tube and he said that a small amount would go a long ways. Dr. Abbe presented specimens of seed growth, showing the inhibitory effect of radium upon such growth. After speaking of the effects of radium upon morbid growths he showed photographs of mammary carcinoma, lupus of ear and temple, epithelioma of the ear, recurrent carcinoma in a scar, tumor of the eyelid, giant-celled sarcoma, exophthalmic goitre, etc., pictures demonstrating the "before and after" condition, proving almost conclusively that certain normal growths could be benefited and even cured by means of radium In most instances the radium rod was simply bound on the skin over the growth and left for a brief period of time, or else the glass tube was plunged into the growth and left for twenty-four hours or less; in all instances reported the effect was very gratifying. He advised the use of radium in malignant growths where surgery was not available.

Dr. Richard said that the strength of the radioactivity could be known

Chicago Surgical Society.

At a meeting, held March 9, 1905, Dr. Nancrede exhibited and reported the following cases: (1) Dermoid [illegible] (2) [illegible] tumor of superior maxilla. (4) Ligation of internal and excision of external carotids for malignant disease. [illegible] articulation of the hip-joint for sarcoma of the femur and tubercular endovaginitis. (6) Extensive plastic operation of the face after removal of carcinoma of the orbit, nose, and face. (7) Rectoplasty for extensive trauma [illegible] (8) Scar carcinoma in the region of the great trochanter. (9) Fracture of humerus with posterior dislocation of the upper fragment. (10) Secondary suture of

ulnar nerve after gunshot injury. Dr. J. E. Summers of Omaha, Neb., read a paper by invitation, on "The Surgical Treatment of Chronic Mucomembranous and Ulcerative Colitis, with Especial Reference to Technique." He discussed chronic primary colitis, primary membranous colitis, and ulcerative colits, and reported eight operative cases. Dr. Van Buren Knott of Sioux City, Ia., read a paper on "Drainage in Diffuse Septic Peritonitis," in which he emphasized the following points: (1) Operations for diffuse septic peritonitis should be made as quickly and with as little manipulation as is compatible with thoroughness. (2) Evisceration, partial or complete, greatly increases shock and the prospects of a fatal result. (3) The general use of clean hot water will most thoroughly cleanse the infected cavity with the least traumatism. (4) Drainage is simplified by collecting the peritoneal fluid at one point where drains may be easily placed. The elevated head and trunk posture followed by the gravitation of fluid to the lower pelvis best accomplishes this. (5) Results following the surgical treatment of diffuse septic peritonitis will be improved should each individual operator adopt some definite form of procedure in such cases which, being well understood by operator and assistants, may be methodically, speedily, and thoroughly carried out.

Treatment of Leprosy by Leprolin.—Norman S. Rudolf calls attention to the fact that a *sine qua non* in the cultivation of the bacillus of leprosy is a medium free from chlorides. In practice a salt-free medium is obtained by the distillation of beef extract with steam. He describes the technique of the process as follows: Small bits of pumice stone are washed and dried in the sun, and are then made to absorb a mixture of one ounce of meat extract to two ounces of water. The stone is then placed in wide-mouthed bottles which are put in an autoclave. Through the stopper of each bottle pass two tubes, one opening into the autoclave and reaching nearly to the bottom of the bottle, and the other leading from the top of the bottle into an adjoining condenser. When all is adjusted and the steam admitted, it passes by one tube to the bottom of the bottle, and rising through the pumice stone, carries with it the volatile constituents of the meat extract, and reaches the condenser by the second tube. The vapor in the condenser yields the salt-free nutrient medium in the proportion of two liters to each ounce of meat extract originally used. The nutrient medium is collected as it flows from the condenser in sterilized Pasteur flasks, which are immersed during the process in a freezing mixture in order to condense some of the volatile alkaloids from the beef, which otherwise would escape. The nutrient fluid is then inoculated with the bacillus of leprosy, and the flasks are kept in an incubator at a temperature of 37° for from four to six weeks. By this time the appearance of the flasks should be turbid with a stringy, white deposit. The contents are passed through a Pasteur filter, and this resulting filtrate is again filtered in the same way. The fluid is evaporated in vacuo over concentrated sulphuric acid, to about one-tenth its bulk. It is then mixed with an equal quantity of glycerine and preserved in an ice-chest until used. This is leprolin. An injection of 10 c.cm. causes a violent reaction in a case of leprosy. Improvement is generally shown first by a return of perspiration to the dry parts, followed by a return of sensation. Next comes a gain in strength and loosening of the contractions of the fingers and toes. Ulceration generally begins healing at once. The nodules and tubercles gradually flatten and disappear. Pain in the limbs usually vanishes early in the treatment. The mental condition and physiognomy improve remarkably, as does the general health. A number of cases have already been discharged as cured. Some improvement has been noted in all cases, while in some cases curative effect has been very marked. In no case has the treatment seemed to aggravate the disease.—*Med. ...*

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

New Instruments.

A READY CONTACT METHOD FOR TESTING URINE.

By P. M. WISE, M.D.
NEW YORK.

It must be true that our forebears cautioned us "take heed of the little things as the great ones take care of themselves." One of these little things which has illustrated the truth of the bequeathed adage, I have practiced with much profit in the matter of time-saving, and although it may not be new or unique, I can find no reference to it in textbooks or elsewhere.

There are few physicians who do not daily, and many times daily, test samples of urine to detect abnormal constituents, especially albumin (proteids). The contact method has largely superseded nitric acid and heat, or has been conjoined at least. The current method, I believe, is to overlay a quantity of pure nitric acid in a test tube with urine, and watch the reaction of its slow diffusion at the point of "contact"; the advantage of this "contact method" lying in the fact that the view comprises the natural appearances of urine and nitric acid with the reaction at contact; conditions for comparative estimation not to be excelled, and emphasizing the appearance of the slightest coagulum.

The present technic in detail is, I believe, to pour a few c.c. of nitric acid (c. p.) in a test tube, and with a pipette allow a small quantity of the urine to flow down the inclined inner surface, slowly, so as to avoid mixing, and to intensify the line of contact. This is well enough in the laboratory, but is awkward at the bedside, and is unnecessary anywhere. Moreover, nitric acid (c. p.) is neither a safe nor a pleasant companion, and its manipulation is not desirable when it can be avoided. Besides, a test tube or its substitute is not always available, especially in case of need.

I have found that a pipette alone gives equally if not more satisfactory results than the method referred to. Instead of nitric acid, I use a reagent first suggested, I believe, by Dr. Lyon, as follows: One part nitric acid and five parts of a cold saturated solution of magnesium sulphate. By grasping a pipette without the suction bulb (or with) as shown

in the sketch, and lowering it into the suspected urine for one-third of its length, placing the index finger over the top and removing from the sample, it will remain one-third filled. Clean pipette with a moist pledget, or hold under a stream, and lower into reagent for two-thirds its length, remove finger and when the urine appears in the pipette replace finger and remove, observing point of contact. Further comment is unnecessary, except that half a minute is ample time for this process, the pipette being the sole instrument to be cleansed. The same procedure is applicable to any contact test, only bearing in mind that the liquid having the higher specific gravity should be the last introduced.

502 West One Hundred and [illegible]

A MULTIPLE VACCINATION SHIELD.

By WM. P. SWETT, M.D.,
SOUTHERN PINES, N. C.

If any of the readers of the Medical Record have had occasion to remove a vaccination shield covering a mass of corruption from the arm of a patient, he will be gratified with the result of a different dressing. I have never known of any one else using this method, but it has proved so satisfactory for years with me that I venture to send the description of it to you.

The accompanying picture was taken the eighth day. One scab was shed the twenty-first day, two the twenty-fifth day, and the last the twenty-seventh day. Multiple vaccination was suggested to me by Dr. Henry A. Martin's son. I have never seen an ulcer by this method, and no sore but healed quickly, a new scab forming when the original was accidentally lost too soon. The vaccinations (insertions) should be an inch and one-fourth apart and the smaller the scarification the better; an eighth of an inch square produces a most satisfactory result. On the sixth or seventh day, or when the local congestion is at its height, bunion plasters should be put on, as shown in the picture. Cut the plasters so that each vaccination is in the center of an opening, and sew the cut edges together; lastly, bevel the felt on the outer edges so that the clothing may ride smoothly over it in dressing and undressing. Should the plasters become detached, a narrow strip of adhesive plaster across the middle and a wider one at each end, encircling the arm and overlapping a little, will keep the dressing in place for weeks if desired. Itching and its results are remarkably lessened.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 15, 1905:

	Cases.	Deaths.
Measles	[illegible]	[illegible]
Diphtheria and Croup	325	31
Scarlet Fever	260	11
Smallpox	2	1
Chickenpox	180	
Tuberculosis	[illegible]	175
Typhoid Fever	16	6
Cerebrospinal Meningitis	182	117
Typhus Fever		
Yellow Fever		
Cholera		
Totals	1,710	350

The Mutation Theory, Heterogenesis, Spontaneous Generation, and the Evolution of Morbid Germs.—Jonathan Wright declares that it is impossible for him to believe that microorganisms have gone on multiplying at the rate of many generations a day since "Creation," without variation or mutation. Neither does he believe that spontaneous generation was a mere phenomenon of a remote geological era, which has never recurred. He continues, that if we are to assume from a priori reasoning that spontaneous generation, archebiosis, heterogenesis, are closely related realities, whose occurrence it remains for science to demonstrate by actual observation, then it is in living protoplasm that we must look for them. But modern bacteriology largely rests upon a technique that includes the sterilization of the nutritive media, in other words, the destruction of living protoplasm by boiling or dry heat. The genesis of new life cannot be looked for from the resultant material. The writer calls attention to this as one of the weak spots in the armor of the modern dogma. He also thinks that Virchow's apothegm, "omnis cellula e cellula," is fallacious. He believes that the liability to error of the vast majority of Bastian's observations is very great with the technique used. In reference to Millican's work, the writer recalls some of Sir James Paget's statements in which he speaks of the frequent inhalation of the germs of contagious diseases. Yet they do not germinate in us, because we do not offer the fitting soil. The writer declares that in spite of culture tubes and hanging drops, there has grown in him a belief in heterogenesis and spontaneous generation. As to de Vries' work, he does not think that it does anything more than extend the essential idea of Darwinism. Although the original scheme of this scientist shows many weak points in its details, the central idea, according to the writer, remains [illegible] (*St. Louis Medical Review*).

The Tuning Fork as an Instrument of Precision in Physical Diagnosis.—Robert N. Wilson shows [illegible] great assistance the tuning fork will be in discriminating between a cavity and other conditions simulating it. If the tuning fork be set in fairly rapid vibration and the [illegible] of the handle be placed lightly upon the thorax, and then be made to approach the bell of the stethoscope which rests upon healthy lung tissue, the note will go through a striking series of changes. In passing the fork from normal to consolidated tissue, the pitch rises, and the note becomes much clearer. Indeed, it may become evident for the first time. If it next passes over a superficial ca[illegible] the note becomes clear, sweet, and musical. This character is never simulated by any other condition. The note can[illegible] (*Medical Record*).

The Prophylaxis of Vesical Disturbances After Gynecological Operations.—[illegible] that the [illegible] micturition experienced by many patients after operations [illegible] ration, is in large measure due to the altered posi[illegible] of the uterus. This is, by the correction of its retrodeviation, brought into such a position that it draws the urethra upwards, and by angulation of the canal causes the urinary obstruction. The condition is the reverse of what is observed in puerperal cases, in which the weight of the enlarged uterus, by drawing the base of the bladder backward, produces a corresponding kinking of the urethra. In order to overcome the fault and to avoid the necessity for frequent catheterization, the author is accustomed after such operations to drain the bladder by a permanent catheter, which is left in position from five days to a week. By this measure the operative field is also relieved of the element of jeopardy, which an overdistended bladder often introduces.—*Zentralblatt f. Gynäkologie.*

Constipation.—Fidey formulates these rules for securing a natural daily intestinal evacuation: (1) The meals should not exceed three a day. (2) Food should contain a considerable bulk of indigestible matter, and be well masticated. (3) A good drink of water should be taken half an hour before each meal. (4) A habit of daily evacuation at a certain hour should be inculcated. (5) There should be no support of the abdominal walls, and no restraint of muscular action. (6) The waist muscles should be regularly exercised, either by systematic movements, the pursuit of sport, or of regular physical work.—*The Hospital.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended April 15, 1905:

MULTIPLE MYELOMA (KAHLER'S DISEASE). A CONTRIBUTION TO ITS SYMPTOMATOLOGY AND ITS MORBID ANATOMY.

By JOSEPH COLLINS, M.D.,
ATTENDING PHYSICIAN TO THE CITY HOSPITAL
NEW YORK.

The disease known as multiple myeloma, myelophatic albumosuria, or Kahler's disease, is one of very great rarity. At least we may so conclude from the few reports in the literature, not more than thirty-nine cases have been recorded at the present time. The case which I now put on record is the tenth to be reported from this country, and the second one which has come under my own observation.

Although Bence Jones had described the peculiar proteid found in the urine of this case in the Phil. Trans. of the Royal Society of 1848, the disease was first described by Dr. W. McIntyre in the Medico-Chirurgical Transactions of London, in 1850. McIntyre designated the changes in the bones of his patient, who had suffered for upward of a year with severe pain in the chest, back and loins, as osteomalacia. In the urine of this patient, Bence Jones found albumose, a constituent which has since been thought to be a necessary accompaniment of the disease. Kahler, after whom the disease is often called, because it was his discussion of the symptoms that called widespread attention to the disease, described his case in the *Prager medicinische Wochenschrift,* in 1889. Between this date, and that of the recording of Dr. McIntyre's case, the history of another case had been reported in the *Zeitschr. f. Biologie,* by Kühne of Heidelberg in 1883. The patient was under the care of a Dutch physician, Stokris, who submitted the urine to Kühne. All these cases had been looked upon as osteomalacia. This is not astonishing, for even to-day, with all our refinement of histological technique to distinguish between osteomalacia and tumor growth in the bones, associated with rarefying osteitis is very difficult sometimes almost impossible. It was then that Kahler reobserving his own case and contrasting it with the others just mentioned, and particularly with a case of malignant disease of the bone-marrow described by v. Rustitzky as multiple myeloma, showed that there was a sameness in their clinical delineation and anatomical findings and classified them under the heading of multiple myeloma. Furthermore, it was Kahler who promulgated the statement, which has since been universally accepted, that the presence of the albumose in the urine described by Bence Jones, is pathognomonic of this disease. In England the disease has been discussed principally by Bradshaw and by Moffatt (*Lancet,* January 28, 1905). All writers on the subject say that the essential clinical features of the disease are pain of the bones, the presence of Bence Jones' albumose in the urine, and gradual dissolution, death being rarely delayed more than a year. For instance, the last writer upon the subject, Dr. S. J. Meltzer (Medical Record, June 18, 1904), says: "The occurrence of albumose in the urine is pathognomonic for this disease. With this knowledge in mind such cases will not escape recognition with the careful physician." Moffatt, who has recently reviewed the subject, says that reports of cases of multiple myeloma without Bence Jones' albumose in the urine should be received with some caution. When no post-mortem was made the evidence is, of course, merely negative, and consequently carries but little weight. And when Bence Jones' albumose was not looked for it may easily have been missed, though present, for even in the absence of serum albumin, seeing that Bence Jones' albumose is redissolved on boiling, its presence might quite conceivably escape notice.

It is because the case which I herewith report negatives the statement that the occurrence of albumose in the urine is pathognomonic. I consider it of much importance. The patient was under the observation of several physicians for nearly two years, all of whom were prejudiced in favor of the diagnosis of multiple myeloma, yet were hindered from making it by the fact that repeated examination of the urine failed to show albumose. A further point of interest in the anatomical side of the case is the extensiveness of the new growth, invading all the bones of the skeleton without the slightest indication of metastasis, although the disease had existed for upward of two years.

The patient, a German, 56 years old, and a porter by occupation, was admitted to my service in the City Hospital, May 12, 1904. So far as could be learned there was little of interest in the patient's family history save that one sister 60 years old had cancer of the breast. His father was a hard drinker and died of some acute pulmonary disease when 54 years old. His mother died at 63, but he does not know what disease she had, but he recalls that she coughed a great deal before she died. One brother died of pneumonia when 33 years old.

The patient himself had had many infectious diseases. When five years old he had "chills and fever"; when 23 years old he contracted syphilis for which he was treated a very short time, perhaps two months; when 24 he had an attack of typhoid fever; when 32, he had an attack of rheumatism and when 40 an attack of malaria. He drank beer and whiskey rather freely every day, and occasionally went on sprees as well.

He dates his present illness from April, 1902, when he began to experience pain in the back and difficulty with his water, which came too quickly. The pain was of sudden onset and of considerable severity. He entered St. Francis' Hospital and was discharged two weeks later unimproved. He felt feeble and lame, but was able to walk with the aid of a stick. In July he went to the German Hospital and after staying there a week was sent to

the Isabella Home, where he remained a month. At this time he had pains in the legs and arms as well as the back. For a short time after this he got along fairly well, but his former symptoms recurring he again went to the Presbyterian Hospital where he remained three months. He was later in the German Hospital, and then in Bellevue Hospital from October, 1903, to May, 1904. I am indebted to Dr. Van Horne Norrie, Dr. W. K. Draper, Dr. F. W. Jackson, of the Attending Staff, and Dr. Smith of the House Staff of Bellevue, for allowing me access to the notes made of the patient while in that hospital. When I first saw him in February, 1904, he complained of pains all over the body, which he described as a dull, excruciating, constant ache, at times heavy and boring in character. It was constantly present, not worse at night. With it there was agonizing hyperesthesia of the legs, and the expression of fear and agony that came into his face when the bed clothes were turned down were interpreted to indicate the profound aversion he had to being touched or handled. In addition to this he has had difficulty in holding the urine, and for the last seven or eight months he has had to pass water at short intervals, often every 10-15 minutes. Thirst is at times excessive. He has been growing steadily weaker and emaciated. For the past six months he has been bedridden. Before he took to the bed he said he had shortness of breath on exertion. He complains of palpitation of the heart at times. When he is kept absolutely quiet he makes little complaint, but when he is moved or handled he cries and complains bitterly and manifests every indication of the most abject fear.

He is greatly emaciated as the accompanying illustration shows. Since the onset of his trouble he has lost 65 pounds. His general appearance is also well shown by the photograph. He is pale, sallow, extremely emaciated and cachectic. The pupils are normal in size and reaction, the scleræ clear and bright, the tongue slightly tremulous, teeth well preserved, the pharynx anemic. There is moderate edema of the feet and ankles, a systolic, soft, blowing murmur heard at the apex is transmitted toward the axilla. The pulmonary sound is accentuated. The heart is slightly enlarged. The lungs are emphysematous. The abdomen, which is emaciated, flabby, sunken, shows no masses, no ascites, no excessive sensitiveness on pressure. The liver is small and not tender. The spleen cannot be palpated. The axillary glands are soft and somewhat enlarged, and so likewise are the inguinal glands, especially of the right groin. There is a mild tremor of the extended fingers. The tendon jerks of the knee and ankle are elicitable, somewhat sluggish, and there is general hyperesthesia both of the surface and the deeper parts of the body. There are symmetrical scars over both tibiæ and the extremities are profoundly emaciated. Repeated and careful examination fails to reveal any irregularity of the surface or enlargement of the bones either of the shafts or of the articulations. Aside from these meager subjective and objective symptoms, nothing could be elicited. The conspicuous feature of the patient subjectively when he came under my care, was that he made no complaint when he was undisturbed, which was the more remarkable as he seemed to be so profoundly ill, and objectively the advanced emaciation and cachexia, and the extreme sensitiveness of the skeleton to contact and pressure.

The information obtained by physical examination was indeed very slight. Aside from the systolic murmur, a peculiar, slight infiltration edema of the back in the lower lumbar region and dullness over the apices of the lungs with numerous râles all over the posterior parts of the lungs, nothing worthy of mention was found. Repeated examination of the urine, and especially to detect albumose failed to reveal anything abnormal save occasionally a trace of albumin. The urine when heated slowly showed no turbidity whatsoever, nor did any of the tests reveal the presence of the albumose described by Bence Jones in 1847, and which is supposed to be pathognomonic for the disease under discussion. It is corroborated also by the reports of the urinary examinations made while the patient was in Bellevue. The patient was seen frequently by my colleague, Dr. Nathaniel Bowditch Potter, and this point especially corroborated.

A few reports of the examinations made of the urine are appended herewith:

Fig. 1.

May 21, 1902: Total quantity, 3½ pints. Pale, straw-color; acid reaction; specific gravity 1,018; urea, 337 gr. No albumin, albumose or sugar. Few hyaline casts and very few granular casts.

September 6, 1903: Clear light amber; acid; 1,015; no sugar or albumin. Few leucocytes and few hyaline casts.

September 9, 1903: Slightly cloudy, amber; acid; 1,020. Very faint trace of albumin; no sugar. Few leucocytes. Very few hyaline casts.

September 14, 1903: Clear, light amber; acid; 1,018. No albumin or sugar. Few leucocytes and hyaline casts.

September 24, 1903: Clear light amber; acid; 1,012. No albumin or sugar. Few leucocytes; epithelium and granular casts.

October 29, 1903: Cloudy, light amber; neutral

reaction; 1,014. Very faint trace of albumin; no sugar. Epithelium and few leucocytes.

October 28, 1903: Straw colored; faintly acid; 1,012. No albumin or sugar. Few leucocytes. Very few granular casts.

October 31, 1903: Cloudy, straw colored; faintly acid; 1,012. No albumin or sugar. Few leucocytes. Very few granular casts.

November 5, 1903: Cloudy, straw colored; faintly acid; 1,012. Very faint trace of albumin; no sugar. Epithelium and few leucocytes.

February 5, 1904: Clear, light amber; acid; 1,015; No albumin or sugar. Very few granular casts.

May 12, 1905: Sp. gr. 1,012; acid. No albumin or albumose; no sugar. Few finely granular casts.

May 17, 1905: Cloudy; alkaline; no albumose; faint trace of albumin; no sugar. Granular casts finely granular. Occasional hyaline cast; no blood.

Blood Examinations:

September 8, 1903: Reds, 4,496,000; leucocytes, 8,100; Hemaglobin, 41 per cent.; differential count, 100 cells; many ring forms, very slight poikilocytosis; no nucleated forms; polymorphonuclears, 60 per cent.; l. lymphocytes, 27 per cent.; s. lymphocytes, 11 per cent.; eosinophiles, 1 per cent.; myelocytes (neutr.), 1 per cent.

October 16, 1903: Reds, 3,944,000; leucocytes, 6,900; hemoglobin, 43 per cent.; differential count, 100 cells; no poikilocytosis; polymorphonuclears, 65 per cent.; l. lymphocytes, 10 per cent.; s. lymphocytes, 23 per cent.; eosinophiles, 2 per cent.; myelocytes.

November 30, 1903: Leucocytes, 11,600; reds, 4,040,000; Hb., 50 per cent.

December 3, 1903: Reds, 4,520,000; Leu., 6,100; Hb., 56 per cent.

January 11-12, 1903: Reds, 4,632,000; Leu., 8,200; Hb., 60 per cent.

May 14, 1905: Reds, 3,480,000; Leucocytes, 8,100; hemoglobin, 48 per cent.; no poikilocytosis.

The accompanying protocol of the autopsy is kindly furnished me by Dr. Horst Oertel, Pathologist to the Hospital, and to whom I am very much indebted, not only for this, but for looking over all the sections of the bones.

Anatomical Diagnosis:

Brain: Apparently normal.

Heart: Brown atrophy, concentric hypertrophy slight.

Lungs, right: Chronic interstitial pneumonitis.

Lungs, left: Chronic interstitial pneumonitis.

Liver: Chronic interstitial hepatitis slight, venous congestion.

Kidneys, right: Chronic interstitial nephritis.

Kidneys, left: Same, less advanced.

Spleen: Chronic splenitis and perisplenitis.

Pancreas: Chronic pancreatitis.

Stomach: Chronic gastritis.

Genitourinary tract: Papiloma of bladder, fibrous prostate.

Other lesions: Glands of lumbar, right internal iliac and right inguinal fibrosis and periadenoid fibrosis. Bones, seat of small, round tumor masses.

Cause of Death: Multiple myeloma; chronic interstitial nephritis.

Autopsy Notes.—Body, 164 cm. height; much emaciated. Skin dry, pale and scaly. Pupils regular, dilated. Slight granular roughening felt on palpating the bones through the skin. On opening the thorax the diaphragm is found at fifth space on both sides. The left pleural cavity is free except in the vertebral gutter and posterior half of the diaphragm. The right pleural cavity contains a small amount of fluid. A few adhesions are found in the vertebral gutter, but most of the lung is free. The heart is small and on opening the pericardium a few extremely thin, smooth, delicate milk-patches are seen, on both the right and left sides. The mitral valve is normal. The chorda tendinæ are thick and of medium length. The papillary muscles are hypertrophied. The aortic valve is thickened at the base and there is patchy thickening throughout, save at the edges which are soft and smooth. The first portion of the aorta has patchy calcified atheromatous plates and larger fatty plates. The aortic valve is 8½ cm. in length and the mitral valve 10 cm. The right heart shows fenestrations in the free edge of the semilunar valve; otherwise it is normal. The tricuspid has large leaflets, otherwise it is normal. The chorda tendinæ and papillary muscles are short and thick. Thickness of left heart 1½ cm. and of right ½ cm. Weight, 270 grams. Muscle deep reddish brown, vessels fairly distinct. Coronary arteries show distinct atheromatous decay, localized patchy, calcified atheroma.

Left lung small, visceral pleura irregularly thickened, very thick over the vertebral gutter (1½ mm.) pale fibrous fissures obliterated by old adhesions. On section there is moderate edema, color irregularly red and white, vessels very distinct. Bronchial walls and interlobar pleura very thick. The glands at the hilus are firm but not increased in size. The larger bronchi contain blood-tinged, frothy mucus, and the mucous membrane is deeply congested. Only the larger vessels show slight atheroma. The right lung is smaller than the left. The pleura is irregularly thickened throughout, of firm consistency and slightly edematous. Otherwise similar to the right lung.

The spleen is very small, the capsule steel blue and thickened. Cut sections show fibrous tissue, lymphoid follicles and vessels very distinctly. The consistency is increased, the weight 100 grams. The cortex of the left suprarenal is irregularly mottled, red and yellow, and distinctly atrophied. The medulla is diminished. The intermediary portion is prominent.

There is very little fat about the left kidney. Its capsule is moderately adherent and its consistency is increased. The surface is slightly granular with irregular gross cicatricial-like contractions. On section the color is deep red and the markings fairly distinct. The cortex is more deeply injected than the medulla. The malphigian bodies stand out conspicuously and are injected. Thickness of cortex is 9/10 to 1 cm. and weight of the kidney 165 grams. The right suprarenal is similar to the left, but smaller. The right kidney weighs only 75 grams. The capsule is very adherent. The surface is finely granular and the consistency increased. On section it is of pale red color, the markings moderately indistinct and the vessels very prominent. The cortex is 4 mm. thick and the malphigian bodies, which are very short, are drawn toward the surface.

The peritoneum which is smooth and shiny, contains no fluid. Large intestine collapsed. The small intestine is moderately distended with gas. There is no retroperitoneal fat. The omentum is thin. The common gall duct is patent, and the contents of vessels at hilus of the liver negative. The liver itself is very small weighing only 840 grams. Its capsule is slightly thickened, its consistency somewhat increased. There is moderate intralobular injection and the lobules are grayish yellow in color. The gall-bladder is filled with a small amount of fluid bile. The mucous membrane is very thin.

The pancreas is small, pale and firm. The vessels and lobules distinct, the ducts patent.

The bladder is small, its mucous membrane thin.

At the trigone there are multiple small polypi, about the size of a pea, 15 to 50 in number, some sessile, some pedunculated. The seminal vesicles are small and their fibrous increase is much increased. The prostate, which is extremely fibrous, is moderately enlarged, especially its lateral lobes. The pelvic glands, which are very marked on the ight side, show extreme fibrous periadenitis. The lumbar glands have some interstitial perifibrosis.

Heart.—This organ shows a moderate atrophy and brown pigmentation of the muscle fibers, with marked interstitial cellular proliferation, and here and there patches of mature fibrous tissue, which have replaced the muscle fibers. The vessels of the heart are thickened, and many of them show circumvascular small round-celled infiltration.

Lungs.—These are the seat of chronic emphysema and marked interstitial growth in places which, as a rule, is fairly cellular, and confined especially to spaces about the vessels and bronchi. There is also considerable stasis of blood. A few of the alveoli contain cellular débris and large round pigmented cells. There is also marked anthracosis.

Liver.—This shows well-marked stasis, moderate atrophy of liver cells, and in places where the stasis is more marked the atrophy is more pronounced. Moderate increase in fibrous tissue of the interlobular spaces. There is moderate round celled infiltration and bile precipitation within the lobules.

Kidneys.—The kidneys present marked stasis, moderate thickening of the vessels and interstitial growth around Bowman's capsule. The glomeruli show cellular interstitial growth and obliteration of vessels, and occasionally hyaline transformation. There is slight parenchymatous degeneration of the epithelium of the tubules.

Lymph Glands.—The lymph glands examined show marked irregular growth of mature fibrous tissue, which penetrated into the glands from the capsules, and replaced the lymphadenoid tissue. The periosteum of the long bones is thickened and is easily elevated. The consistency of the long bones is very much diminished. There is no distinct line of demarcation between the medulla and the bone proper. Taken together, the bones present a moderately calcified, partly pinkish, pale or yellowish mass. There is scarcely any normal medulla, its characteristic appearance being altered by the pale, calcareous mass which has replaced it. This same change seems to exist in all other bones examined—calvarium, long and flat bones.

*Microscopical Examination.**—Sections from the bones show extensive loss of the bone substance proper, with diffuse cellular growth, mostly small round cells, in the widely dilated interlamellar spaces, producing in this way large and small cavities, irregular in shape, bounded by thin or thicker remnants of lamellar substance, which contain the new growth. Within these spaces the arrangement of the cells is partly of an alveolar character, partly more diffuse. Where larger cavities have formed there is an entire loss of the Haversian system. The new growth is formed by small or larger round cells, intermingled with more elongated, almost spindle-shaped cells, which at first present a distinct concentric arrangement around the vessel, later take on a diffuse growth. This is associated with the formation of a pale, hazy, intercellular substance, the amount of which varies, it being much greater in some of the cavities than in others. It is obvious that this has filled the Haversian spaces, and after causing a resorption of the bony substance, it has succeeded in replacing it.

In the large spaces there is to be observed a peculiar arrangement of the growth, which is characterized by the formation of smaller or larger spaces, lined by endothelium, surrounded by the more diffuse cellular growth. They have all the appearances of an attempt at formation of vessels, but for the most part they do not contain blood. The cells which form their walls have a decidedly fibroblastic appearance. Towards the periphery again are found larger and smaller round cells. The nuclei of the cells appear pale and vesicular, with rather small, irregular chromatin contents and frequent mitotic figures.

Bone substance and marrow are equally involved in an active, diffuse, or more nodular cellular proliferation, of a supplanting character, and the loss of bone substance here gives the impression that it is due to foreign invasion. There is no preponderance of gutter figures, grossly or histologically, no hemorrhagic infiltrations, no red or yellow marrow.

On the other hand, the bone marrow itself shows marked myeloid proliferation, replacing red cells and fat in the affected areas. From the histological findings of the sections first examined, it appeared that the growth was of a mixed, partly round, partly spindle-celled variety, and never going on to the formation of mature tissue, was intimately connected with the Haversian systems and the cell forms genetically related. (Fig. 2.) But the examination

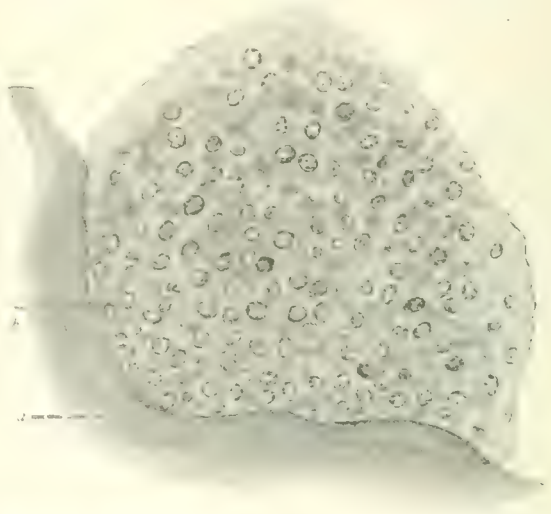

Fig. 2.—(a) Remnants of old bony structure; (b) Infiltrating tumor growth. (c) Old Haversian canal infiltrated. Leitz. Obj. 3, Ocular 4.

of a large number of sections, especially those which are apparently closer to the marrow, made that point somewhat doubtful. (Fig. 3.) While unquestionably there exists a marked formation of spindle and epithelial cells, and the attempt at formation of new blood-vessels, which is especially distinct in some portions of the tumor, large cells of a distinct myeloid appearance play a very essential rôle in this tumor formation, and in some parts they seem to predominate, to the exclusion of the others.

The picture, then, on the whole, is somewhat complex. As Dr. H. Oertel says: "Whether we have to deal with a peculiar mixed myeloma is still an open question, difficult to decide. However, there is no doubt that we have a tumor formation which at present may be grouped as *myeloma*, for this term has been used as one of situation rather than histogenesis. Zeigler and others regard them as simple

* For this report I am indebted to Dr. B. C. Crowell, Resident Pathologist to the Strecker Memorial Laboratory of the Hospital, and to Dr. H. Oertel, the Pathologist.

round-celled sarcomata, while recently an attempt has been made to limit that name to diffuse or nodular infiltrations of distinctly myeloid character. And here is the peculiar feature of this case, for it appears to be related to both varieties, and I would at present not attempt to make a more specific classification."

Dr. Harlow Brooks, to whom a series of sections were submitted, is of the opinion that the growth is unquestionably a myeloma. Of the etiology of the disease nothing is known. It has been met with more often in males than in females, and in most of the cases it occurs in the second half of life. The constant symptoms are pains in the back and sides. There are increasing weakness and anemia, and though there may be temporary remission of the acute symptoms, they invariably recur and progress to a fatal end. Spontaneous fractures of the ribs

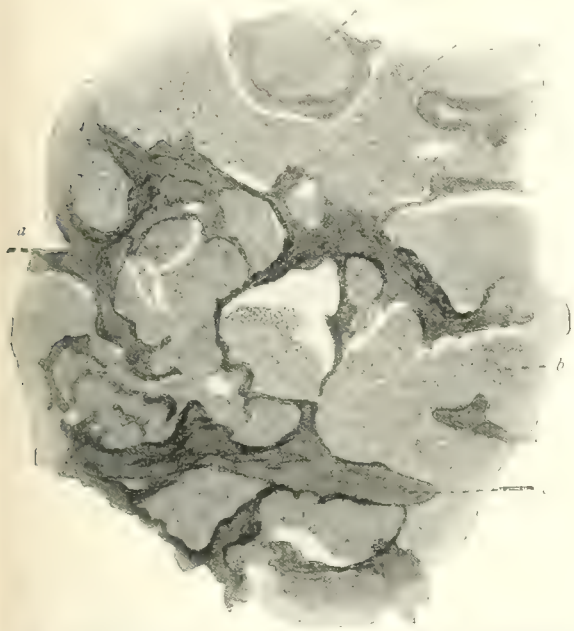

Fig. 3.—Same as Fig. 2, under higher magnification. Leitz. Obj. 6, Ocular 4. (*a*) Remnants of old bone structure; (*b*) Cells of infiltrating tumor growth showing general myeloid character of the cells.

have been noted in many cases, and also tumors growing from the ribs and deformity of the dorsal and lumbar vertebræ. The urine is unlikely to attract attention until the patient comes under treatment for his other symptoms, but occasionally the patient notes the urine is turbid.

There are certain clinical features of the case that are worthy of emphasis. In the first place there was no deformity or alteration in the contour of the bones to be made out during life. Despite the fact that the substance of the bone was so largely replaced by new growth, and the existence of rarefying osteitis to a high degree, there were no indications that there had ever been fractures or dislocations. In the second place, at no time was the peculiar peptone, supposed to be pathognomonic of the disease, found in the urine, and whereas other cases have been reported in which albumose was not found in the urine, this would seem to be the first case which was for a long time under observation in which repeated examination of the urine, extending over several months, during which time the disease was fully developed, failed to find albumose. It is because of this, rather than to discuss the anatomical features of the new growths, that the case is recorded.

37 West Fifty-fourth Street.

LET THE LUNGS ALONE IN CONSUMPTION.

By WOODS HUTCHINSON, A.M., M.D.,
PORTLAND, OREGON.

There is no more fascinating study than that of the development and changes in the conceptions of disease in medical thought. This is peculiarly true of consumption. First conceived as a general disease, as its name in every language implies, a wasting, a decline, "phthisis," *"Schwindsucht,"* "consumption," without any serious attempt at localization; next in the days of Laennec, as a local disease of a special organ, and finally within our own days as the work of a particular parasitic organism, finding its favorite nidus in that organ, its history has been an epitome of the evolution of scientific thought.

Each of these conceptions, and the work done under it, has added much that is valuable to our knowledge of the disease, but while now prepared to recognize them all as true, we can see with equal clearness that no one of them contains a complete conception of the disease in itself. Of course, the tendency has always been in each of these phases to claim that in that conception lay the whole truth and the sole rational method of approach to treatment. This delusion, however, rapidly had the breath battered out of it by the resistless shower of the blows of stern experience, beginning curiously enough with the latest and newest.

We have learned by bitter experience that we must practically ignore the bacillus in our treatment of the consumptive. Are we not coming to the same point of view with regard to the lungs? It is certainly a most curious paradox, that, while fully and firmly convinced that the bacillus tuberculosis is the cause of consumption, and that without it consumption could neither be transmitted nor developed, we yet find ourselves utterly unable to utilize or even to recognize this important and fundamental fact in any way in our treatment of the patient himself, invaluable as, of course, it is in the problem of prevention and transmission. To this position, however, we have been driven by the remorseless logic of events and our utter inability to discover as yet any drug or agent which will check the development of tubercle bacilli within the human body without injuring the tissues more than it does the bacillus. Valuable as the different serums are for diagnostic purposes, and helpful as some of the later forms appear to be in hastening the recovery of the patient under the open air treatment, yet it must be said that they have as yet achieved no specific or reliable position in the treatment of this disease. And the few which do hold the confidence of even a fraction of the profession act entirely by stimulating in some way the resisting powers of the tissues and not by preventing the development of the invading germ.

In my judgment, we are coming to almost an identical attitude with regard to the remedies which are supposed to have a remedial action upon the lung itself, from creosote to the cabinet and from exercise to altitude. Certainly, it is true that the one and only method in which the profession has an atom of confidence, the only one which has been known to cure the disease, utterly disregards both the bacillus and the lung. And now, with the characteristic tendency of the human mind, after having been driven to this position, much against our will, by the fierce buffets of bitter experience, having, by an incessant and enthusiastic testing of forty foolish things, been driven back upon the one rational procedure, we begin to cast about in our minds for explanations of the rightness of our new-found po-

sition. Fortunately, they are not far to seek; indeed, some of them are so obvious that we wonder that we never saw them before, and had not reasoned out our position in advance, instead of having been ignominiously driven into it by the knout of successive failures.

First of the various reasons for letting the lungs alone in the treatment of consumption, is the fact which is more and more clearly recognized every day, that consumption is not properly speaking a disease of the lungs, but merely a local (pulmonary) expression of a disease which involves the entire system. The consumptive is tuberculous to his finger tips, the disease chiefly focalizing itself in the lungs. This was long ago proven by bacteriologists, when it was shown that no matter by what route the tubercle bacilll have entered the system, whether by food, inspired air, hypodermic injection, or surface wounds, they have a deadly faculty of making their chief lodgment in the lungs. Time and again animals have been made tuberculous by feeding them upon infected food; they have developed and died of pulmonary tuberculosis. On most careful examination after death it has been impossible to detect any lesion in the intestinal wall, and in many not even an involvement of the mesenteric lymph nodes. It is now, in fact, universally admitted by experimenters that the tubercle bacillus, introduced into the system of an animal by whatever route, will first show itself in a recognizable manner in the organ in that animal which is most susceptible to the disease, this organ varying somewhat in different species, as I have elsewhere shown.[1]

In mammals, generally speaking, it is the lung which is the special point of affinity of the bacillus; in birds, on the other hand, this is one of the rarest sites of development, while the liver is almost invariably most seriously involved. In fact, it will be remembered that Behring's latest theory of the port of entry of the tubercle bacilli places it almost exclusively in the intestinal tract. For some reason or another the lung seems to be a point of least resistance to the lodgment and multiplication of the invading organisms, not merely in tuberculosis, but also in pneumonia and bubonic plague in man, anthrax in cattle, glanders in horses, and swine plague or hog cholera in pigs.

Equally overwhelming in itself, and most convincing, is the further evidence that this localization of disease in the lung is not affected in the slightest by any conditions which appear especially to irritate, attack, or even interfere with the expansion of the lung as such. But that susceptibility to all of them and to the involvement of the lung in all will be markedly promoted by any conditions which tend to lower the general resisting power and vigor of the entire system, such as overcrowding, underfeeding, or overwork.

Further, we are daily confronted by the paradox of a consumptive patient whose pulmonary lesions, as evidenced by all physical signs, are at a standstill, or even progressing, for weeks after his appetite, weight, and general strength show marked improvement, ending ultimately in recovery. Cure the body and it will cure the lungs.

To regard consumption as primarily or essentially a disease of the lungs is as illogical as to term Bright's disease essentially a disease of the kidney. The treatment of either disease from this point of view alone is predestined to failure.

The one organ which is chiefly and constantly defective in the consumptive is the heart. The typical "poitrinaire" ("lunger") is the individual with large lungs and small heart. This is absolutely supported by my study of the incidence of the disease in animals.[2] The pulse is our best guide in consumption.

The second reason why it is well to let the lungs alone in consumption is that they are practically beyond the reach of any remedy which we possess. Germicides intended to kill, or even seriously to discourage, the bacillus *in situ,* are, of course, out of the question. Remedies which act chiefly upon the movements of the lung, as digitalis does upon the heart or purgatives upon the bowels, we have none. We have not even remedies, so far as at present known, which can reach the lung, as certain drugs can the kidney, by dint of being excreted by it.

We have absolutely no tonic or alterative which will improve the general nutrition of the lung, or increase our appetite for air in the slightest degree, except such as work simply through their effect upon the general system.

Nor are we much better off as regards remedies to be used in direct frontal attack as local applications. Our class of so-called expectorants has almost entirely faded into air under the calcium light of modern investigation. A few of them, like certain salts of ammonia, may perhaps have a slight liquefying effect upon the bronchial mucus; but the vast majority cannot be proven to have any effect whatever upon any part of the respiratory tract, except that above the level of the larynx. Most of them are at bottom simply more or less mild narcotics or local anesthetics to the upper third of the respiratory tract, and practically none of them, except opium, reaches below the epiglottis, and this, the only cough sedative which produces any effect, produces almost invariably an injurious one in tuberculosis.

Not even our sprays, our inhalations, and our vapors will enable us to penetrate much further. It has now been shown by repeated and careful experiments that none of these reach below the level of the epiglottis, and most of them go no further than the middle of the pharynx. Intratracheal injections are the only known means of bringing remedies into direct contact with the bronchial surfaces. A few of the so-called expectorants and "lung tonics" of the resinous, or aromatic, group, by impregnating the air of the mouth and nasopharynx with their fumes for a considerable time after they have been swallowed or inhaled, may perhaps be drawn down into the trachea; but when we remember that the tidal air in ordinary respiration probably seldom reaches below the middle of the trachea, and that the fullest inspiration can inhale particles no further than the middle of the bronchi, all further interchange of air in the lungs being by gaseous diffusion, or ciliary movement, it will be seen how utterly impossible it is to cause any of these "healing" remedies to reach the "sore spots" in the apex. So that as far as medication, either direct or indirect, is concerned, the lungs are practically utterly out of our reach, and it is probably a mercy that they are so.

The third reason for letting the lungs alone in consumption, is that in the vast majority of cases, so-called pulmonary gymnastics and the demands made by them upon the lungs to expand beyond their natural limit, as is done in most methods where the air tension is artificially increased, as by breathing out against resistance, simply drive the infectious material into hitherto uninvaded areas of the lungs.

Nature's method of cure in this condition is the familiar one of surrounding the zone of attack with exudate, and changing this exudate gradually into a fibrous barrier, in which the organisms of the infectious material are imbedded. Forced expansion

of the lungs injuriously interferes with this process, breaking up such protective adhesions as have already taken place, and scattering the infectious material abroad in the lungs. So far as these procedures are based upon the ground that the lung of the consumptive is distinctly deficient in size in proportion to his weight and needs expanding, they are, in my judgment, in error, for as pointed out long ago by Fothergill and Beneke, the actual total capacity of the chest of the tuberculous individual is probably as large as, if not greater than, the average for his weight, rather than less. The chest of the consumptive is narrow and round but remarkably long. What it lacks in breadth it appears to make up in length. We should develop his body so as to give his superfluous and emphysematous lung tissue plenty to do, rather than balloon his lung.

Abrams pointed out some years ago that the condition of the consumptive lung previous to the attack of the bacillus is one of expansion instead of collapse. And careful observation of my patients in this regard since hearing his suggestion inclines me to agree with him.

A form of emphysema is the condition preliminary to attack, instead of a condition of collapse of the air cells. The ghastly failure of the cabinet to expand the lungs of the consumptive, by creating a vacuum around his body and causing him to swell out, as it were, like a wrinkled apple under the bell of the air pump, needs only to be alluded to along with the other lessons of history.

Another interesting fact which should give us pause in our enthusiasm for expanding the tuberculous lung, is the remarkably beneficial effects which have come from the enforced or educational stopping of cough in these cases. Begun simply as a means of preventing the dissemination of infection, or even for the pitiful purpose of attempting to conceal the existence of the disease from the eagle eye of the keeper of the average boarding house or hotel at health resorts, it has been found to be of marked benefit to the patient himself. The reason being that it husbands instead of exhausting the last drop of his strength; it permits the inflamed area of the lung to enjoy that rest, which inflamed tissue all over the body absolutely demands; and it eliminates the possibility of driving the infectious sputum into other bronchial passages by the tremendous back-pressure developed during the spasm, or sucking it into new areas of the lung by the gasping, almost whooping inspirations which follow or intersperse the paroxysms.

Moreover the measures which have been adopted for so-called expanding of the chest have been radically wrong, in that they address themselves to the wrong diameter. The general impression, both among the laity and in the profession is that the chest of the consumptive is flattened, that is the anteroposterior diameter is the one which is diminished or deficient.

As I had the honor to report some seven years ago,[3] actual measurements with the calipers of the chests of tuberculous patients, show that just the reverse of this is the fact, and that it is the transverse diameter that is deficiently developed. The accumulation of a series of nearly 500 measurements upon the consumptive chest since that time by other observers and by myself[4] has absolutely supported this position that the chest of the consumptive is round instead of flat, Gymnastic exercises calculated especially to develop the chest as such, in my judgment, do more harm than good; their one benefit being such exercise as they may give to the general muscular system and through these to the circulation, wherever this may happen to be indicated. The only pulmonary gymnastics of any value are those that develop the entire body and general vigor. But these are only of value before the disease has developed, or after convalescence has set in.

This brings us to the most serious objection to any form of gymnastics, pulmonary or otherwise, in tuberculosis; and that is that, whereas in former years we regarded exercise as one of the chief means of cure, now we are firmly convinced that it is distinctly injurious and that absolute rest is indicated in any case in which the afternoon temperature rises above 100°. We seem to be practically reduced to the position that special exercises devoted to the expansion of the chest are irrational in principle, the chest being probably already equal, in form and volume in proportion to weight, to that of the normal individual, if not in excess of it, although the actual expansion may be less than that of the normal individual.

Such forced expansion as can be obtained in the lung is harmful rather than beneficial, in that it tends to promote the spreading of the infectious material into deeper areas, to break up the newly formed connective tissue in which the healing tuberculous foci are being imbedded, and to interfere with such steps as nature may be already taking through pleuritic or other adhesions to put the damaged parts at rest. The only benefit, in fact, of these exercises is in promoting general nutrition and quickening the respiration and circulation, and this we now regard as an injury instead of a benefit in cases showing any degree of activity or progress.

In fact, our phthinologists, as they term themselves, have swung to the other extreme, and are now strapping down the affected side of the chest, particularly where pleuritic involvement has occurred, with broad bands of adhesive plaster applied *en cuirasse,* and even throwing loops over the opposite shoulder which can be cinched together with bandages, thus exerting very considerable degrees of pressure upon the chest wall. There can be little doubt that this procedure in properly selected cases adds much to the comfort of the patient and, if his condition has been detected early enough and he is placed on an intelligent open-air and overfeeding course, he will probably recover under this straight-jacket treatment.

But other enthusiasts are equally sure that the affected areas, especially in the early stages, need to be ballooned out forcibly, so instead of strapping the affected apex, they strap the base and lateral wall of the chest below it, thus, as they believe, causing the apex to balloon out , thereby greatly increasing its air supply and consequent circulation. As these men are able to report equally good and flattering results by this method of ballooning, in connection with the open-air treatment, it arouses suspicion in the mind of the unprejudiced observer that it is this common factor which is responsible for the cure in both sets of cases; and that both groups of patients would probably have recovered in the same proportion, if their chests had been left entirely alone.

Certainly both of these methods cannot be right at the same time. They have this advantage over the old methods of forced expansion, whether by the cabinet or gymnastics, that they do no positive harm. Either of them may be safely resorted to whenever they appear to increase the comfort of the patient or to sharpen his expectation of a cure.

But the evidence which should give us most thoughtful pause of all in our campaign of direct attack upon the lung tissue as such, and our endeavors to promote and increase oxidation in the tuberculous patient, is that contained in the remark-

able and most unexpected findings of Robin and Binet[5] in their investigations as to the actual gaseous interchange in the consumptive. These researches with their most unexpected and, to my eye, most important results, have never attracted the attention which they deserve, although published now nearly four years ago.

By prolonged study and estimation of the amount of oxygen consumed and carbon dioxide given off by ten tuberculous patients, who were most carefully studied in properly constructed respiratory chambers or cabinets, they arrived at the surprising result that nine of them showed, instead of a diminution of normal oxygen intake and carbon dioxide output in proportion to their body weight, a marked excess.

In exact figures the total quantity of air expired was 80 per cent. greater than that passing through the lungs of an individual of the same weight in perfect health; the amount of carbonic acid exhaled was 64 per cent., while that of oxygen consumed was 70 per cent. greater, leaving a considerable amount of oxygen to be absorbed by and fixed in the tissues. A year later they made a completed report before the Academy of Medicine of Paris,[6] in which they had passed upon a much larger number of cases, which absolutely confirmed their former position; namely, that the consumptive instead of being an individual whose respiratory processes are deficient, is one in whom they are in marked excess.

So far as I have been able to discover these researches have not yet been repeated by other observers, with the exception of certain of their students and assistants; but inasmuch as they are the only results upon record in which the actual gaseous interchange of the consumptive has been put to an accurate test, and the amount of increase shown is so enormous as to be utterly incapable of explanation by any simple oversight in the method or error of personal equation in observers of such well-known scientific standing and reputation as both of these men, they certainly are entitled to a strong presumption in favor of their correctness.

What makes their findings so much the more interesting is that having once discovered this excessive overdraft, so to speak, on the part of the consumptive lung-furnace, they began comparing the condition of affairs in this regard in patients who were the subjects of other chronic diseases, particularly of rheumatism and gout, with the interesting result of finding that in both of these two conditions the proportion, or percentage, per kilo body weight of oxygen intake and carbon dioxide output fell distinctly below the normal, though not so markedly as that of the consumptive rose above it.

In another group of chronic cases, including pneumonia, neuroses, cancer of the stomach, and visceral ptoses, the respiratory exchange was in some cases slightly exaggerated and in others normal. So that so far as this series of cases goes we seem to be brought to the position that tuberculous patients have a very marked increase of gaseous pulmonary interchange, while gouty and rheumatic patients have a less distinctly marked, but still definite and constant decrease, and other classes of diseases depart but little from the normal.

Still another step was taken by these investigators, and that was the examination of two groups allied to the tuberculous, namely, the scrofulous and the descendants of tuberculous parents. In the latter of these groups a majority of the cases showed a well marked exaggeration of the respiratory exchanges. That is, of thirty children of consumptive parents, twenty-one of whom were in good health, nine subjects of various intercurrent diseases, but none showing any signs of tuberculosis, respiratory exchanges were markedly increased in eighteen. A similar increase, though less marked, was found in a group of some thirty cases with marked depression of general vigor due to such causes as overwork, grief, financial reverses, alcoholism, and sexual excess, usually regarded as predisposing to tuberculous infection.

With great enthusiasm and energy MM. Robin and Binet extended their investigations to the influence of various factors in promoting or diminishing this increased pulmonary ventilation, which they regarded as one of the necessary precedents of tuberculous infection. Heat and dryness of the air were found to have variable effects, with no uniform tendency in either direction. Warmth and moisture of the air were found in the majority of cases to increase the gaseous interchanges. Cold air increased the interchange in some, diminished it in others, thus making a negative record. It was found to vary at different mountain altitudes without any uniform effects, and the few patients who were sent from the city to live in the open air at the seaside, were found to have their gaseous interchanges diminished. The one factor which invariably and under all conditions was found to diminish these gaseous interchanges was rest! And this was particularly marked when the rest was combined with the recumbent attitude. The authors finally conclude with the statement that in their judgment these researches warrant them in the position that "an exaggerated tendency on the part of the organism to fix oxygen and form carbonic acid, that is to say, to consume itself, constitutes one of the characteristics of the propathic state, or soil, of phthisis."

This position is certainly a sufficient reversal of our former beliefs to give a distinct shock to current theories. So radical a departure is it that we must insist upon a thorough corroboration of the work by other observers and the accumulation of a sufficient body of data to render its correctness unassailable. But it strikes me as having so many points of support in our clinical and therapeutic experience of the last two hundred years as to give it the air of a strong probability of truth.

First of all it explains a striking, and in spite of its passing into popular conceptions, really undeniable element in the makeup of the disease, and that it, the extraordinarily rapid wasting of the body-tissues which takes place in tuberculosis. Let any one merely look at the face of the consumptive in the late second, or early third stage, with his flushed cheek, his brilliant eye, his translucent skin, his emaciated yet eager look, and the thought rises unbidden at once that he is literally burning himself up. In the second place, it explains, as no other hypothesis has yet, the extraordinary fact that not only will our consumptive patients lose weight with remarkable rapidity, but that they will gain it with almost equally astonishing speed.

The consumptive comes to be, to me, more steadily year by year, an individual who is not simply deficient, but remarkably unstable in bodily weight. Nearly any remedy which can be given to a consumptive short of the third stage, nay almost any change of climate or environment or of surroundings and conditions in any respect, may cause him to gain from eight to fifteen pounds inside of three or four weeks. A thing which is practically impossible to effect in eight out of ten perfectly healthy individuals.

This is, of course, one of the reasons why such an innumerable host of remedies of all descriptions have succeeded in getting a reputation in tubercu-

losis. It also agrees with the well-known clinical fact that a mere increase in weight as such, though encouraging, is by no means a reliable sign of actual improvement in the patient's condition. Thirdly, it at least throws some light on the singular fact that while tuberculosis is regarded as distinctly a disease of lessened vitality, or lowered appetite, of defect instead of excess, the remedies and the foods which have been found most useful clinically are those which distinctly tend to check metabolism and clog combustion processes, namely, first and most important of all, fat of every description, especially in the redoubtable form of cod-liver oil, then tar, creosote, iodoform, ichthyol, the cacodylates, and other forms of arsenic. (These last, by the way, were specially tested by Messrs. Robin and Binet and found to diminish markedly the "pulmonary ventilation" both in individuals who were overworked and in tuberculous subjects.) It has always been to my mind a singular fact that drugs, such as cod-liver oil and creosote, which could not be taken by the healthy individual without nauseating him, destroying his appetite and making him "bilious," will be consumed in large quantities by the tuberculous patient, not only with comparative relish, but with positive increase of appetite and improvement in nutrition. Instead of their stimulating effects it would appear to have been their checking and retarding effects that are beneficial in consumption. The delusion that creosote and iodoform act as antiseptics in any way was of course exploded years ago.

Last, and most important of all, it throws a flood of light upon the fact that the two remedies which have been alone found of the slightest dependability and permanent effect in the treatment of tuberculosis, namely, rest in the open air and overfeeding, are precisely the ones which most surely and constantly diminish this excessive respiratory interchange.

It has always been a matter of amazement to the profession, indeed I have heard it seriously urged as an objection to the rationality of the open-air and overfeeding treatment, that we can administer to a wasted and emaciated consumptive, weighing perhaps barely 110 to 120 pounds, with little or no appetite, sluggish bowels, broken sleep, and everything that one could well imagine to diminish his appetite and powers of digestion, quantities of fats and proteids, in the shape of cream, milk, raw eggs, raw beefsteak, ham, and bacon, which a perfectly vigorous individual in full active work and weighing 160 to 180 pounds could not consume without becoming bilious. Especially as this mere shadow of an individual consumes these enormous amounts of material while absolutely confined to his chair or his bed and forbidden under the strictest penalties to take any exercise whatever. Only an enormous and overwhelming excess of pulmonary combustion in the consumptive, can account for this extraordinary capacity for fat and proteid digestion in excess.

In short, from this point of view it would appear highly probable that our tuberculous patient is to be regarded in the light of one who, to use a very rough simile, is pouring nearly half the heat of the fuel which is burned in his body furnace up the chimney, in the form of smoke. That the food which he takes into his system, instead of being assimilated and decomposed by anaërobic processes in the body cells, is burned in the blood and in the lungs. Any means, therefore, which will tend, so to speak, to clog the throat of his chimney and prevent this fatal escape of heat and energy, whether by shutting down the draft by drugs like creosote, iodoform, cod-liver oil, and arsenic, or by pouring in an enormous quantity of food rich in heat value, so that sufficient energy can be derived to run the body-machine in spite of the large waste up the chimney, will tend to restore the balance of his gaseous interchange and enable him to return to the normal.

That in the small number of gouty and arthritic patients tested the pulmonary interchange fell distinctly and constantly below the normal, throws into curious relief the old clinical belief that these two diatheses were in some way antagonistic.

If anaërobic metabolism be in excess in the gouty, it may account for their tendency to break down the nuclei of their body-cells and form uric acid under the invasion of toxins, whether endogenous or exogenous.

Derangement of this anaërobic metabolism is probably the secret of fever, and this, of course, is due to toxins, which would place gout as a special form of mild febrile reaction.

The fact that out of thirty children of tuberculous parents eighteen showed a marked increase of pulmonary interchanges, would support the view of Robin and Binet, which seems to me probable upon other grounds, that this tendency really precedes the actual development of the infection, and constitutes something nearer than anything yet discovered to the much discussed, so-called "pretuberculous" state. The position cannot yet be accepted as established beyond question, but it certainly seems to fit in better with the results of careful and intelligent clinical observation than any other which has yet been suggested.

608 MARQUAM BUILDING.

AËROPHAGIA AND FLATULENCE.

BY C. D. SPIVAK, M.D.,
DENVER, COLO.

ALL hollow organs of the body contain normally a certain quantity of air. The digestive tube is no exception to the rule; the mouth, the stomach and the intestines each contain atmospheric air, either pure or mixed with some other gases. On introducing a tube into the esophagus, stomach or colon there is, as a rule, an escape of air. It is highly probable that the presence of air in the digestive tract is necessary for the accomplishment of their respective digestive functions. We know also that the escape of a certain quantity of air from either of the two extremities is not only compatible with good health, but is absolutely essential to well being, as any one who has watched closely the workings of his own engine during twenty-four hours may easily convince himself. Occasional puffs, buccal or rectal, audible or not, are physiological and therefore useful; though neither ornamental nor always agreeable.* They are the manifestations of

* Tastes differ. In China, for instance, not only is belching not considered inelegant, but on the contrary, it is raised to the heights of an institution, a national ceremonial. Instead of making after-dinner speeches, after the viands are discussed and the traditional rice is reverently ingested, the host rises and excuses himself before the invited guests for having invited them to so shamefully

the mobile equilibrium of the organism, and, as Spencer puts it in his definition of life, "a continuous adjustment of internal relations to external relations." When these relations become for some reason disturbed the process of adjustment still goes on, but it is of an abnormal nature. It may be that in the future we shall find that some morbid conditions of the gastrointestinal tract are due to deficiency or absence of atmospheric air in certain portions of the alimentary tube, and that some therapeutic method will be devised to supply the same. At present, however, we are acquainted with only one phase of the morbid process, namely, the presence of excessive quantities of air in the stomach and intestines.*

An accumulation of gas in the stomach or intestines in quantities sufficient to cause disagreeable sensations to the patient, and to give a tympanitic note on percussion is called "flatulency" or "tympanites." These terms are interchangeable, though the latter refers particularly to a retained and distending, the former to a moving and escaping gas. "Meteorism" denotes the acute stage of tympanites. "Borborygmus" is a condition wherein the accumulations of air and fluid are in a state of motion through peristalsis, felt by and audible to the patient as well as to the observer.

Flatulent dyspepsias were known to and described by the ancients, and the most fanciful explanations were given as causative factors. It is only in the nineteenth century that a careful study was begun. Combalusier in 1827[1] reported a case of tympanites wherein the evolution of gas was so great that it gave rise to the displacement of the abdominal viscera. At present we distinguish several distinct forms of gastrointestinal disturbances accompanied by flatulency.

Flatulency has been noticed in women during menstruation and at the menopause; preceding attacks of malaria; following exertion, such as running upstairs or trying to catch a train; in cases of cardiac disease—"heart wind," of Mitchell Bruce;[2] in peritonitis; in diarrhea, or following the excessive use of purgatives; in cases of thoracic aneurysm;[3] accompanying severe pain, as attacks of migraine, or biliary or renal colic; in the aged, especially towards evening;[4] in intestinal ulceration, especially of tuberculous or dysenteric origin; in hysteria; in cases of occlusion or stenosis of the intestines; following spinal lesions; in volvulus or dilatation of the stomach; in cachectic and chlorotic individuals.

Pneumatosis embraces a group of cases in which there is an excessive accumulation of gas in the stomach following immediately or soon after meals, the patient being unable wholly or in part to belch it up. In typical cases the epigastric region is found greatly distended—so much so that the contour of the stomach stands out most prominently. The patient experiences a sensation of distress and distention, marked want of air (asthma dyspepticum), a feeling of utmost anxiety, palpitation, etc.[5]

Eructation is marked by frequent discharges of gas from the stomach, or excessive belching. Hippocrates, and after him many others, described *morbus ructosus*. As a rule, wherever there is eructation, tympany of various degrees is present. It may accompany varied affections of the stomach or intestines, or it may occur idiopathically; in the latter case it received the name of "eructatio nervosa."

The question naturally arises, Whence does the gas come? The sources are as follows:

1. Fermentation.—Food may undergo acid fermentation (lactic, butyric) or alcoholic fermentation.

2. Putrefaction.—Albuminous substances may undergo decomposition.

3. Alimentary.—Certain articles of food and drink produce flatulency, as cabbage, beans, peas, carbonated waters, etc.

4. Intestinal Respiration.—Flatulence due to exchange of gas (CO_2 and N) between the blood and the contents of the stomach and intestines. This is supposed to be the explanation of the great evolution of gas occurring after severe pain, major operations or in neurotic individuals. Nothing definite is known as to the source of the gases eructated in such cases, but it is surmised that they are discharged from the blood. Brinton[6] calls the adherents to this theory "superficial observers and lax reasoners." He claims that the physiology of the digestive canal not only justifies, but demands a very different interpretation of the facts. His explanation is as follows: The bulk of a gas depends upon the pressure to which it is exposed; to double the pressure of a cubic inch of gas would diminish its bulk one-half; or, conversely, to halve the pressure would double its bulk. The gases within the digestive tube are exposed to the pressure of the abdominal muscles and that of the muscular parieties of the tube. The distention of the gases, therefore, is due to diminished pressure, or, in other words, to muscular relaxation.

5. Aërophagia, or swallowing of air. Since the subject of aërophagia has not received the attention it merits from the medical writers in the English language, we consider ourselves justified in devoting to it the greater part of this essay.

Dejardin[7] was the first to report a case in 1814 of a conscript who, in order to avoid military service, swallowed large quantities of air, which produced abdominal tympanitis. Magendie[8] in 1815 affirmed that the ability of swallowing air is easier than it was thought to be. Bouvier[9] in 1826 wrote a memoir on the subject and reported cases. Pierquin[10] in 1830 employed air-swallowing as a therapeutic measure in two cases—a man aged sixty, with cancer of the stomach, and a girl aged twenty-one, suffering from autumnal fever with gastric irritation. Andral[11] in 1848 remarked, "There are individuals who possess

meager a repast, being dead sure that their hunger was not appeased nor their thirst quenched. The guests protest vehemently; they vie with each other in praising the variety and delicacy of the many dishes, and after having exhausted their flowery oriental vocabulary, place their hands upon their bellies, approach the host and belch up into his face, loudly and repeatedly, thus bringing forth from the bottom of their stomachs conclusive and convincing proof that they are indeed fully satisfied.

*The theory that the excessive accumulation of gas in the intestinal tract in certain acute diseases is to be looked upon as a beneficent agency, was recently propounded by Dr. H. C. Wetherill (The Beneficent Agency of Peritoneal Exudates, Adhesions, Aperistalsis, and Meteorism in Peritonitis, *American Medicine*, August 27, 1904). In studying the subject of secondary phenomena of peritoneal infections like adhesions, tympanites, and aperistalsis, he arrived at the conclusion that they play a beneficent part during the acute stage. He draws the analogy from exudations and adhesions which are conceded to play an important part in protecting the patients from the diffusion of the infection, as exemplified in a walled-off appendix or tubo-ovarian abscess. He is convinced that tympanites, through ballooning the intestines and thereby increasing intraabdominal pressure, serves the same beneficent purpose "in bringing loop to loop closely about the infecting focus and splinting the abdominal wall and diaphragm, so that even the respiratory movement shall not disturb the newly established quarantine station." The theory of Dr. Wetherill seems to be so sane, rational and ingenious that there is no doubt it deserves careful consideration by the medical profession, and the mistreatment of tympanites following acute abdominal infections will, I hope, be modified in accordance with this rational view-point. At present we cannot apply this theory to chronic cases of tympanites, but it certainly furnishes a new basis for further research.

the faculty of swallowing air and thus produce tympany." Chomel[12] refers to "direct introduction of air from the mouth into the stomach by a sort of deglutition," but he is rather inclined to accept the theory of Girardin that the mucous membrane of the stomach and intestine continuously exhale gas.

Longet in 1861[13] remarked in his text-book of Physiology, "There are individuals who can introduce this fluid (air) into their stomach, even into the intestines." Heusiger[14] in 1862 described a "rare form of spasm," and wonders whether "cribbing is possible in man." Demarquay[15] in 1862 remarked that "air may penetrate into the stomach with liquids or alone by a particular method of deglutition which many persons can perform." Falke[16] in 1863 described "cribbing in man." Willieme[17] in 1866 opposes the theory of internal generation of gas, and ascribes the numerous and rapid eructations seen in certain persons to alternate deglutition and expulsion of atmospheric air. Grisolle[18] writes in 1869, "Air can be introduced into the stomach during respiration and more so during deglutition of saliva and food." Piory[19] in 1871 cites the case of an army officer who swallowed constantly great quantities of air which "caused violent pain, and a moment later, fortunately for the patient, excessive and noisy eructations followed. Eichhorst[20] asserts that he could hear the noise which the successive deglutitions produced, and witnessed the distention which followed. Quincke[21] and Rosenthal[22] in 1889 discussed the subject extensively in their respective contributions. Bouveret[23] deserves credit for his elaborate discussion of the mechanism of this affection, as well as for the name aërophagia, which he gave the disease.

Since that date the following observers have contributed their mite to the elucidation and casuistry of aërophagia: Aubert,[24] Obici,[25] Pitres,[26] Wyllie,[27] Dupaquier,[28] Vauthey,[29] Southerland,[30] Lange,[31] Hayem,[32] Raymond and Janet,[33] Vincens,[34] Lyonet et Vincens,[35] Mathieu et Follet,[36] Soupalt,[37] Deguy,[38] Bouveret,[39] Regnalt,[40] Perrody,[41] Mathieu,[42] Morange,[43] Trambley,[44] Stern,[45] Zweig,[46] and Puritz.[47]

The phenomenon of swallowing air is not limited to man alone. Other animals, especially the horse, are subject to this affection. In fact, the affliction was recognized long ago in the horse. Mr. A. M. Farmington, Acting Chief of the Bureau of Animal Industry, U. S. Department of Agriculture, in reply to my inquiry, writes as follows: "Indigestion or dyspepsia was formerly attributed as the cause of air-swallowing, but later observers have more properly classed it with the vices, and in the same category with a considerable number of other whims, bad or vicious habits, resulting, in most instances, from idleness, which the horse, free from restraint, incessantly repeats without any other motive in reality than the gratification of desires which finally become imperative, but which always interferes with his complete serviceability. The modes by which the horse accomplishes the act of air-swallowing are known by the names of 'cribbing' and 'wind-sucking.' Usually, in cribbing, the horse takes a point of support or contact for his upper incisor teeth, which causes an abnormal wear of the teeth, and the vice can thus be detected. Less frequently he cribs in the air, without taking a point of contact, and is what is called a 'wind-sucker.' To crib in the air, the animal begins a rapid up-and-down movement of the lips, then suddenly lowers his head—sometimes to the level of his knees—and swallows a mouthful of air; most frequently with the production of a guttural sound, which has sometimes been wrongly interpreted as an eructation. When the effort is not successful, and is confined to the simple act of deglutition of saliva, the attempts are renewed until the desired satisfaction is secured.

"Cribbing with support differs from the foregoing in that, in order to execute it, the inferior extremity of the head is supported or braced by means of the incisors upon a resisting body of some kind, such as a post, the bottom or edge of the manger, a window sill, a cross-piece of a hay rack, a shaft or pole, the halter or harness of his mate, etc. When subjects are prevented cribbing on a support they will sometimes learn to crib in the air, and *vice versa*. A colt of a cribbing mare has been known to acquire the vice considerably before the age of one year. The muscles used in air-swallowing are not different, nor is the mechanism apparently different, except as above noted, from the act of deglutition generally. Remedies consist in the removal, so far as practicable, of objects that may serve as a base of support for the inferior extremity of the head, and the buckling of a strap around the neck just below the gullet. These methods, however, do not effect a cure, but only prevent the act while in use. Surgical operations have likewise failed to yield permanently satisfactory results." For information as to details in regard to the operation, Mr. Farmington refers to two articles by Professor Harger of the Pennsylvania University, Veterinary Department.[48]

As regards the mechanism of air-swallowing in man the views of the observers differ. The majority agree that the air enters the stomach in the same way as food, *i. e.*, by an act of deglutition. In the words of Lauder Brunton,[2] "When a small quantity of saliva is swallowed at a time it does not completely fill the pharyngeal cavity, and air is actually swallowed along with it. Frequent swallowing of saliva, therefore, is, according to his view, the main factor in aërophagia. This view is also shared by Deguy,[38] who included also the swallowing of smoke by smokers. Aubert[24] considers aërophagia as a voluntary act and of gradual acquirement. The mechanism is the same as in swallowing of a bolus of food. The difference between the alimentary and the aërial bolus is this: "The alimentary bolus having passed the anterior pillars, ceases to be under the influence of volition, whereas a bolus of air can easily be expelled as long as it is in the pharynx, with but a little more difficulty when it reaches the esophagus, and probably as long as it had not traversed the cardia. While a swallow of liquid, or morsel of food, descends easily into the stomach, it is difficult to swallow one mouthful of air. When one bolus of air is swallowed, it is felt to go down slowly, as it is impossible to push it quickly except by a series of deglutitions rapidly following one another, by the *vis a tergo* which one bolus exerts upon the other."

Beuveret[23] does not think that air-swallowing is a simple physiological act of deglutition. He ascribes it to a clonic spasm of the pharynx. The characteristic trait is the sudden and spasmodic deglutition which drags into the esophagus a certain quantity of air, and from there it is forced into the stomach. The violent eructations interrupt for a time the convulsive movements of deglutition, and expel a part of the accumulated air. Thus is produced a continuous circulation of gas from the pharynx into the stomach and *vice versa*, which is accompanied by two distinct sounds, one corresponding to the ingestion and the other to the expulsion of air. The sounds differ in frequency and character. While the deglutitions are short and rapid, from 46 to 60 to a minute, the eructations are but few and longer.

Oser[49] gives an ingenious explanation of the mechanism. He ascribes it to aspiration: "Suppose that through the contraction of the circular fibers the stomach is emptied of its contents, and then the layer of longitudinal fibers contracts, the stomach at once expands, and its lumen is re-established. In such event, if the cardiac orifice is open or but feebly closed, the air from the esophagus rushes in, and is in its turn expelled during the next contraction. The stomach with the esophagus act as a Politzer bag; at each compression of the stomach the air rushes out, and at each relaxation the air is aspirated."

Pitres[26] defines eructation as denoting "a sonorous expulsion from the mouth of gas contained in the stomach or pharynx and esophagus." He claims that there are two origins of eructation; one is gastric and the other is pharyngeal. "The air contained in the pharyngoesophageal cavity is during eructation expelled from the mouth by the contraction of the constrictor muscles of the pharynx. But suppose that at the very moment when these muscles contract the buccal orifice is found closed, the air thus shut in on all sides may recoil towards the lower third of the esophagus; and since the cardia, not being guarded by a sphincter muscle, is easily dilatable, the gas may, therefore, penetrate into the stomach without meeting any resistance."

Another theory is similar to the aspiration theory of Oser, the mechanism being thoracic. "When the chest is dilated, the glottis remaining closed, the intrathoracic cavity becomes forcibly enlarged, and all the organs of the mediastinum find themselves in the midst of a negative pressure. Each reacts in its own way; the esophagus opens up and the external air rushes into the cavity. As soon as the thoracic aspiration ceases, the air enclosed in the esophageal cavity is driven into the stomach, through the feebly resisting cardiac orifice."

Wyllie[27] describes aspiration or sucking of air as follows: "Under normal conditions the esophagus is collapsed and is under a more or less distinct positive pressure from the weight of the atmosphere which acts upon it through the thickness of the structure of the neck; but if the neck muscles are strongly contracted, the chest walls raised and expanded, as in forced inspiration, and the glottis is kept closed, there is formed a negative pressure in the esophagus which allows of air being sucked in from the mouth, and the air can be at once expelled again with a loud eructation." Both Wyllie and Sutherland have noted that the muscles of the neck of such patients are prominent and powerful. Wyllie deserves credit for his classic description of a modification of the act of true swallowing, which he termed "air gulping." We will quote verbatim: "Let me try to make the distinction between the two. In the act of true swallowing a wave of contraction sets in from the dorsum of the tongue, and proceeds backwards to the fauces and esophagus; the larynx being, at the proper moment, pulled forward and upward, and closed against the entrance of food by its protecting valves. Before this wave of contraction the bolus is driven onward into the esophagus. The gulping of air, on the other hand, is accomplished by a process essentially different. Here the tongue is placed in the same position as for the pronunciation of the letter 's,' a position in which the tip and edges are applied closely along the upper gum, so as to prevent the escape of air either forward or laterally. Behind this margin of contact the cavity within the mouth and pharynx is then filled with air from the larynx; and this air is at the same time imprisoned in the cavity, owing to the elevation of the soft palate, which shuts off communication with the nares, and the firm coaptation of the vocal cords, which shuts off communication with the trachea. Thus imprisoned on every side, the air in the cavity is then, in the act of gulping, put under strong and sudden compression by the elevation of the larynx and dorsum of the tongue. Under this strong compression it forces a passage for itself into the cavity of the esophagus, entering the upper end of that tube with a noise not unlike that of a slight eructation. Having got the air into the esophagus by this process of gulping, the patient, if he wishes to do so, can then expel it, by putting pressure on the esophagus within the chest. This he can do by making a slight expiratory effort with the glottis closed. The air then escapes with the characteristic noise of a true eructation. Or, if the patient chooses to do so, he can refrain from eructating, and go on simply gulping air until he has caused a large quantity of it to pass into his stomach. Nearly every one can gulp down air into the esophagus, and bring it up again in eructation in the manner I have now described. With practice, one can produce a loud eructation for each gulp of air; and some hysterics, owing to constant practice, can in this manner produce about thirty loud eructations per minute."

Linossier[50] deserves credit for having been the first to approach the subject of aërophagia from the standpoint of merycism—the regurgitation of food, its remastication and subsequent reswallowing. I take the liberty of quoting the following: "I have often been struck with the similarity between hysterical aërophagia and another neurosis, whose mechanism I have studied, namely, merycism. During the act of rumination, one can observe distinctly the two phenomena which characterize hysterical aërophagia, namely, the swallowing of air and its consecutive expulsions. Although these phenomena are to a certain extent masked by the regurgitation of food, nevertheless they are demonstrable. Applying the ear to the epigastric region, one hears immediately preceding the act of regurgitation a sound produced by a bolus of air entering the stomach. It is, therefore, clearly a combination of aërophagia and eructation. In our case the rejection of the food was always accompanied by the discharge of considerable quantities of gas; the longer the time after the meal the less food was regurgitated, so that the last regurgitation was purely gaseous. It becomes, therefore, a question whether the mechanical affection which produces rumination produces also hysterical aërophagia. What is it, then? Our experience permits us to make the following résumé: The first time, the diaphragm is lowered and the inspiratory muscles contract, the glottis remaining closed. A relative vacuum is thus created in the thoracic cavity, which favors the entrance of air into the esophagus. A small quantity may force itself through the cardia and penetrate into the stomach. The second time, the contraction of the inspiratory muscles become greater, while at the same time the abdominal muscles contract to such an extent that by the widening of the esophagus and the constriction of the stomach between the diaphragm and the abdominal muscles, the contents of the organ are ejected into the mouth."

Linnosier, therefore, arrived at the conclusion that aërophagia is nothing else but gaseous merycism, or, in other words, that the mechanism that produces regurgitation of food produces also the regurgitation of gas.

The objection raised that merycism is a congenital affection, and therefore a physiological phenomenon, does not hold good. Linnosier and Lemoine[44] have established the fact that there are two kinds of merycism—simple merycism, usually congenital, or

appearing at an early age, entirely independent of digestive disorders, and pathological merycism, a sequel to acute or chronic diseases, usually following in the wake of some digestive disorder. They have based their conclusions upon the study of thirty tracings made at the laboratory of Arloing in collaboration with Guinard. The objective signs they have demonstrated are as follows: "The patient lying horizontally on his back, a slight inspiratory movement could be noticed, or, properly speaking, a dilatation of the thoracic cavity. At the same time the entire abdominal parieties were noticed to bulge out, especially at the epigastric region, where a round tumor came into relief, which was nothing else than a distended stomach. Immediately after, one could hear a gurgling sound in the pharynx, while the abdominal parieties and the epigastric region resumed their former positions, the abdomen becoming even somewhat retracted. Finally the alimentary bolus came into the mouth with such force that, although the lips were closed, the fluid would escape through the labial commissures. We have auscultated on many occasions at the time of regurgitation, and we could hear a slight sound of gloo-gloo at the time when the base of the thorax became dilated and the epigastric region bulged out. Furthermore, the expulsion of gas was always considerable. Towards the end of digestion, the eructations were mainly gaseous. The above studies were corroborated by Chauveau and Toussaint[44] in their studies upon ruminating animals."

We see, therefore, that two kinds of phenomena contribute to the accomplishment of the act of merycism, one active and the other passive. The active consists in the depression of the diaphragm and the contraction of the abdominal muscles, both of which produce a void in the thoracic cavity, and the contraction of the abdominal muscles which compress the stomach. The passive phenomena consists in the elongation and widening of the esophagus and the diminution of the lumen of the stomach.

Corlet[44] has devised an apparatus (see Fig. 1), which demonstrates that thoracic aspiration alone is sufficient to bring up the stomach contents into the mouth:

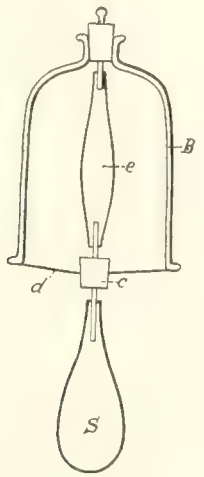

Fig. 1.—Corlet's apparatus; *c*, cork closing rubber dam, *d*, which represents the diaphragm; the glass bell, *B*, represents the thorax; *e*, esophagus; *S*, stomach.

Upon pulling the cork *c*, the vessel *e* fills up with water, contained in *S*.

Tramblay[44] has studied the influence of inspiratory muscles in four cases of aërophagia by the aid of a registering apparatus attached to the abdomen and larynx, and his investigations confirm the findings of Chauveau and Toussaint.

The composition of eructated air has been analyzed by Hoppe-Seyler,[51] Popoff,[52] Ewald and Rupstein,[53] and many others. Their investigations have uniformly demonstrated that the eructated air from the healthy stomach or in simple dyspepsia approaches in composition atmospheric air, containing, namely, nitrogen and oxygen, with an admixture of but a small quantity of carbon dioxide, the latter being derived from the decomposition of the carbonates in the food or in the alkaline saliva. It is only when fermentative changes are going on in the stomach that the gas contains, in addition to the above named, also hydrogen in appreciable quantities, and, in rare cases, marsh gas and sulphuretted hydrogen. Cases in which the eructated air contained an inflammable gas were reported in the seventeenth century by Pisani,[54] and in the last century by Ewald,[53] McNaught,[55] and others.

The quantity of eructated air differs in accordance with the number of deglutitions and eructations. In a case reported by Cortellieri[56] his patient managed to eructate 2,500 times in one hour. The quantity, therefore, must have been enormous. Bardet estimated the amount eructated by one patient in a few hours as 200 liters.

Lauder Brunton[1] enumerates the conditions which give rise to frequent swallowing of air: (1) a continued flow of saliva into the mouth; (2) a sense of irritation and tickling at the back of the throat; (3) a feeling of acidity in the stomach, and (4) a feeling of weight or oppression at the epigastrium or across the chest. The first three points are self-evident, since these conditions necessitate the frequent swallowing of saliva. The fourth point—a feeling of weight or oppression at the epigastrium—is explained in this wise: This feeling is due to irritation of the vagus, as we know from Czermak's[2] experiments. He had an exostosis on one of his cervical vertebræ, and by compressing the vagus nerve between his fingers and the exostosis, he could stimulate it so strongly as to stop his heart. Such stimulation produced also a feeling of constriction (Beklemmung). But irritation of the vagus can be produced in other ways than by compressing its trunk. Depressing emotions, such as sorrow, appear to act on the nerve centers in the medulla from which the vagus springs, and it may be stimulated from many parts of the body, and notably from the stomach. As Kroneker[2] has shown that its action on the heart is temporarily abolished by the act of swallowing, we would naturally expect any one suffering from the feeling of thoracic oppression or constriction due to irritation of the vagus, would swallow frequently, in order to obtain relief. With reference to the oppression of the chest caused by grief when frequent swallowing is resorted to, Brunton remarks that it is so well known that it has come to be popularly expressed in the phrase, "swallowed his grief."

Deguy[38] and also Quinke[21] has seen cases of aërophagia in smokers who swallow the smoke. They educate little by little the smooth fibers of the esophagus, aided by the property of nicotin to contract those fibers, and then ultimately such subjects retain the habit of swallowing air without smoking. He mentions also chronic granular pharyngitis, which is in accord with the second point of Brunton. He refers also to individuals who bolt their food, and suffer from epigastric distress after, who in order to avoid hiccough swallow air so as to be able to find relief in successive eructation. All observers agree, however, that aërophagia is a nervous disorder, and is part and parcel of *eructatio nervosa* referred to above. We can therefore say that aërophagia is found in hysteric, neurasthenic and dyspeptic patients. It is found in children and in adults,

and in both sexes, although the young and the female sex predominate in point of numbers. The examination of the stomach contents may and may not reveal any deviation from the normal; nor is the mobility of the stomach any criterion. The sensibility of the epigastric region is rather increased. In many cases pressure over certain areas of the gastric region produces eructation *(points eructogenes*)*. Baudouin[62] can produce eructations at will by pressing the pit of his stomach.

We must distinguish two kinds of aërophagia—involuntary and voluntary. The involuntary occurs, as a rule, during an attack of violent hysteria. The attacks last from a few minutes to twenty-four hours. They are spasmodic in nature, and nothing can arrest them. Examined during an attack, one notices that the larynx executes the movements of deglutition—abrupt, rapid, involuntary; forty to sixty to a minute. From time to time the deglutitions are interrupted by loud explosive eructations. They are less in number as compared with the deglutitions. On auscultation during deglutition a gurgling sound may be heard over the esophagus, and an amphoric sound over the stomach. The abdomen is tympanitic; the patient feels a sensation of great tension and fullness. As a rule, these patients do not suffer from indigestion. All unpleasant symptoms cease as soon as the attack is over, nor do the attacks occur at night.

Voluntary aërophagia is usually found in neurasthenics and dyspeptics. By voluntary we do not mean that the patient is conscious of the fact that he swallows air, but because the act of taking in the air is under the control of the patients; for as soon as the patient is told how the wind got into the stomach he is at first surprised, but after an effort is able to modify the habit or stop it entirely. As a rule, the trouble is chronic, constant, and seldom of a spasmodic or violent nature. It is a sequel to some form of dyspepsia. The way this habit is acquired is somewhat as follows: The majority of dyspeptics suffer from a sense of fullness after meals. They ascribe it to an accumulation of gas, of which they wish to rid themselves by belching. But they do not succeed, and therefore they begin to go through the form of belching, first by imitating the sound, and then eventually succeed in swallowing air and then belching it up. Many patients lie down and pat their bellies, knead the stomach, and roll from side to side in order to induce belching. These patients find out themselves their eructogenic points. Soupalt,[38] on applying the stethoscope to the precordial region of one of his patients, produced a volley of belching. As we know now, many of our so-called automatic acts which we perform daily without giving them a thought were at first voluntary acts, and as the neurologists tell us that all the various forms of nervous twitchings (tics) are, at the beginning, voluntary acts, so it is with aërophagia. What was at first a voluntary act, done with a certain purpose in view, has become after many thousands of repetitions a vicious habit.

The diagnosis of aërophagia is very simple indeed. One should bear in mind that aërophagia is made up of two distinct parts: (1) The act of deglutition, single or repeated, and (2) eructations less frequent but louder. The up-and-down movements of the pharynx at each are characteristic. Cough and hiccough can hardly be mistaken for aërophagia, the first being an expiratory and the other an inspiratory act.

In flatulent dyspepsia, when fermentation is known to exist, the coexistence of aërophagia may be diagnosed by washing out the stomach. If the phenomena recurs it is due to aërophagia. The belched-up air is odorless in aërophagia. Patients with relaxed gastric musculature suffer from distention of the stomach after meals due to the small quantity of air ingested with the food. They belch quite frequently, but this cannot be mistaken for aërophagia, because the characteristic deglutition of air is absent, and because they do not belch at any other time except immediately after meals.

Since in most cases aërophagia is a voluntary act, when its mechanism is explained to the patients they can suppress it. If the habit has grown on them to such an extent that they have lost control over themselves, all that is necessary is to prevent them from swallowing air, which can be accomplished either by keeping the mouth open by means of a gag, or by stopping up the nostrils.

Treatment.—In involuntary aërophagia usually found in hysterical patients, the treatment is uncertain. Isolation, suggestion, tonics, massage, hydrotherapy, avoidance of intellectual work, etc., are indicated.

In voluntary aërophagia treatment as a rule is successful. It is sometimes sufficient to make the patient understand the origin of his disease, and explain to him that the affection is entirely under his control, and that what seems to him to be an involuntary act is simply due to habit; such patients, if they are intelligent enough, will learn to break up this vicious habit.

In the case of less intelligent patients, the treatment is more difficult. It is sometimes necessary, in order to convince the patient, to have him keep his mouth open for half an hour at a time, as recommended by Penzoldt.[57]

Quinke[21] had obtained good results from introducing a soft, thick sound into the esophagus by analogy with catheterization in an irritable urethra. In cases in which the abdominal walls are relaxed, a suitable bandage is of service. Washing of the stomach had a good effect on one of Penzoldt's patients. As to medicaments, Ewald[58] uses morphine injection. Oser uses sodium bromide, and recommends arsenic, beladonna atropine or chloral in small doses. Boas[59] recommends the pill of extract of Calabar bean, 0.3; extract of belladonna and extract of nux vomica, of each 1.0; liquorice powder and sugar, sufficient to make 50 pills; Sig.: one pill three times daily.

Van Valzah and Nisbett[60] advise an intragastric spray, which they believe is the most valuable single remedy. They use warm water, followed immediately by cold water, or a solution of silver nitrate. Mathieu used chloroform water. Since many patients with aërophagia suffer at the same time from gastrointestinal disturbances, these affections should receive attention. Catarrh of the pharynx and any other coexisting trouble should be corrected.

From a study of the literature and of my own cases, reported elsewhere,[61] I have arrived at the following conclusions:

1. Swallowing of air in small quantities is a normal phenomenon.

2. Abnormal swallowing of air may be voluntary (hysteria), and involuntary (dyspepsia, idiopathic).

3. Air may enter the stomach by swallowing, aspiration, or gulping.

4. Cases of aërophagia are not as rare as the earlier writers used to think.

5. Aërophagia, although at the beginning makes "much ado about nothing," and is, as a rule, a sequel to some other affection, yet when it is let alone it

*Pitres suggests the name of "aërophagenic points," since the act of taking in air precedes that of its expulsion.

may, in its turn, produce grave symptoms and undermine the health.

6. Aërophagia, tympanites, nervous eructation, pneumatosis, and merycism have an etiological relationship.

7. The best treatment in voluntary aërophagia is to impress the patient with the fact that he can stop it if he will. For otherwise "they have sown the wind, and they shall reap the whirlwind."

THE CONDUCT OF THE PERINEAL STAGE IN NORMAL LABOR.*

By B. A. FEDDE, M.D.,
BROOKLYN, N. Y.

It seems that among primitive peoples, and up to little more than two centuries ago among civilized races, the one and only thought among practitioners of the obstetric art was to terminate labor as soon as possible.. The only end in view was the birth of a living child, with the preservation of the mother's life. None seems to have questioned the perfection of nature's process in natural labors, or the almost inevitable occurrence of an uncertain amount of injury to the maternal parts.

Perhaps instinctively some measure of prevention was effected by the ancient method of delivery upon the lap of the midwife, whose thighs gave support to the stretching perineum and perhaps to some degree retarded the process. In other places women were delivered upon a small mound of fresh earth. Later appears the obstetric chair, however, and with its adoption this support disappeared. The use of the labor stool persisted almost through the eighteenth century. Wilhelm Joseph Schmitt (1760-1827) was one of the first to advocate discarding the appliance.

That such a detail as preservation of the perineum should for so long a time remain undeveloped is not much to be wondered at, however, when one considers that well into the seventeenth century, even in France, which stood in the medical van, obstetrics was practised exclusively by midwives whose method of assisting labor, when they did anything at all, comprised only abdominal compression and kneading or manual dilatation of the vagina. They "worked in the vagina in a way to make one's hair stand on end, oiling poulticing, fumigating, etc., in

* Read before the Norwegian Hospital Alumni Association.

order to facilitate labor; they gave all sorts of cordial and oxytocic remedies and constantly employed the labor-stool." (Baas.) The pioneers who ventured into that province had the much more serious problems of dystocia to solve before they could be expected to turn their attention to the improvement of eutocia.

Mauriceau, in 1695, reports the operation of episiotomy as performed, not to preserve the perineum, but in an ineffectual attempt to overcome obstruction due to a rigid coccyx. He describes his method of delivery in this case as a manual dilatation of the vagina and vulva in advance of the head, the hand being well lubricated with olive oil. Evidently no perineorrhaphy was done, for he reports applying a pessary for descensus uteri some time afterward. Further on in his book of observations on obstetrics he reports being consulted by three women with complete lacerations, whom he dissuaded from perineorrhaphy, as the scar would inevitably give way in subsequent deliveries.

Torriano[1] has this advice to give: "Head coming down quick—keep the hand against the perineum lest it tear, and mind to lubricate the parts." Even as late as 1797 Hamilton[2] describes the conduct of labor as follows: "When the parts are violently stretched, the perineum may be gently supported during a pain, and a counter-pressure is generally employed when the labor is rapid; but it should be remembered that this support is only useful as it retards labor, which is often inconvenient and sometimes dangerous. A laceration of the perineum is a very rare occurrence, and generally the consequence of previous disease. It is therefore doubtful how far a hazardous expedient is to be recommended to obviate an uncertain accident." Apparently he is speaking of complete tears, or obstetrics has become a lost art; for the most modern writers on the subject admit a percentage of fifteen unavoidable tears up to thirty-five or more, the usual average in one hundred primiparæ.

In the early part of the nineteenth century, Jörg of Leipzig advocated the removal of forceps before completing delivery of the head, and the use of birth-cushions to save the perineum. It was soon recognized that direct centerpressure on the perineum exercised a crushing and disintegrating force, and this was replaced by counterpressure on the presenting part.

V. Ritgen (1787-1867) seems to have been one of the earliest to exercise any ingenuity in preserving the integrity of the pelvic floor. He advised "lifting the head upward and forward through the vulva between the pains, by pressure made by the tips of the fingers upon the perineum behind the anus close to the tip of the coccyx." (Lusk.) Rectal expression, advocated by Olshausen, followed next. Of the modern methods, the following are the most notable: Goodell hooks two fingers into the anus and draws the perineum forward during a pain, to remove the strain on the thinned border of the vulva; Merkert-schiantz advocates bilateral pressure on the perineum during the pains to diminish the tension on the median line, where rupture usually occurs. A modern mechanical modification of this consists in the use of broad adhesive straps passing from one side of the perineum across to the opposite buttock, as advocated by Noble.[3] In Tucker's perineal guard or "shoe-horn" it is difficult to see any advantage except the abolition of friction between passage and passenger.

In general, the principles of procedure are to secure slow, full dilatation before delivery, to occupy the subpubic space as far as possible, and to deliver between pains by the smallest circumference of the fetal head. The degree of tension during dilatation should be estimated by sight (the danger point being reached when the structures become ischemic) and by a finger laid along the rima pudendi. With regard to delivery between pains most authors claim the advantage to be based upon a supposed greater extensibility of the parts during relaxation; but a little thought will show the fallacy of this. Physiology teaches us that there is an increase in extensibility with the other changes during contraction of a muscle; so that with increasing weight a point is reached at which there is actual lengthening during contraction (Weber's paradox); and it is self-evident that the fibrous tissues contiguous to muscles will undergo no change of intrinsic qualities with contraction of the muscle fibers, so that the advantage must be ascribed rather to the slower rate and better control of dilatation and delivery.

I wish to describe a method employed in forceps cases at the Lying-In Hospital, which I have never seen elsewhere mentioned. It seems eminently rational, is easy to execute, and remarkably efficient. It was advocated in forceps cases and in primiparæ by Dr. Asa B. Davis of the attending staff, whom I believe to be the author of it. I am indebted to him for kind permission to publish it.

If one looks carefully at the classical Schultze illustration of delivery in the occipitoanterior position, the attention may be arrested by the great *longitudinal* stretching of what may be termed the perineal portion of the posterior vaginal wall, besides the circumferential dilatation that it must undergo. Now an elastic tissue stretched in two directions at right angles to each other will naturally tear sooner than if force is employed in only one direction. This, I take it, is the principle underlying Dr. Davis' method.

It consists of arresting the progress of the head by direct pressure when the biparietal diameter has passed the ischiopubic rami and before it has reached the rima pudendi; then by gentle manipulations with the other hand—thumb and fingers on the opposite sides of the vulva—slipping the labia first over the parietal eminences, then backward over the forehead and face without allowing the head to extend until it is fully delivered. By pressure back of the anus with the hypothenar eminence the head meanwhile is maintained in flexion close under the pubis. In practice one receives the impression that tension actually diminishes with the progress of delivery.

My own practice, which I have extended to all cases, is to give chloroform during pains in the latter part of the second stage. When the head begins to distend the vulva, the patient is turned on her side with a pillow between the knees. The chloroform is handed over to the nurse, who administers it according to specific directions given from time to time. Just before delivery, when the parietal eminences have passed the pubic rami, it is ordered pushed to the point of entire cessation of pains, the head is steadied, and the vulva is slipped over the parietal eminences and the face as described. Chloroform is then withdrawn, the woman is turned on her back, coils are felt for and taken care of, and the mouth is cleansed of mucus. Usually there is some delay about the return of pains; they may be stimulated and aided by friction and pressure upon the fundus. Within reasonable bounds delay at this point is free from danger.

Frequently the shoulders will enlarge a tear or cause a fresh one. Rarely the hips and still more infrequently the placenta may act similarly; there should therefore be no remission in attention after the head has emerged.

Lusk advises applying the hand in such a way as to lift the shoulder upward and at the same time furnish a bridge over which it can glide. Edgar[4] recommends delay until the shoulders have nearly rotated into the anteroposterior diameter, then by lifting the head crowding the anterior shoulder up behind the symphysis. This presents the cervico-acromial diameter at the outlet instead of the bisacromial. The posterior shoulder is born spontaneously, or by aid of gentle traction upon the head, after which the anterior shoulder is allowed to emerge, aided, if necessary, by gentle traction downward.

In some cases it may be advisable to repeat the principle of head-delivery for the shoulders, keeping the woman on her side until the child has been born, and by manipulation slipping the perineum backward over the acromion and hips in succession as they appear.

A CASE OF PREMATURE SEPARATION OF A NORMALLY SITUATED PLACENTA.

By J. WIRT ROBINSON, M.D.,
CHICAGO.

Such an occurrence is of interest as it is rather infrequent, and the etiology is not very clear. In the recent literature we see records of even more cases of placenta previa than of premature separation of a normally situated placenta.

Goodell,[1] in 1869, collected 106 cases, and in 1901 Holmes[2] added 200 more to the list. Recently Macam[3] and Colclough[4] have written excellent articles on the subject.

My case was that of Mrs. G. S., who is 30 years old, married, occupation that of housewife, and of English nativity. She gave the following history: Diseases of childhood included measles, diphtheria, German measles and scarlet fever. Outside of the menstrual history she has been well since then with the exception of an occasional cold. When menstruation began she suffered from dysmenorrhea. Having obtained no relief from the family physician, she consulted Mr. Lawson Tait, who curetted and amputated the cervix with the result that the dysmenorrhea was relieved. Five years ago she was married, and two years later she became pregnant and was delivered at full term. From what I can learn, the labor was normal except that the cord was wrapped around the child's neck and caused strangulation. Whether death was due to the fault of the doctor or not, I am unable to determine. The puerperium seems to have been normal. Nearly two more years had passed when I first saw her. Examination showed bleeding from the vagina, the hemorrhage being easily recognizable but not large in amount. The cervix was not dilated. Analysis of the urine did not reveal any renal disturbance. The specific gravity was 1018, urea 1.6 per cent., and there were no casts nor albumen. The history showed that the time was near the end of the thirty-seventh week. The only exertion she had had was using a sewing-machine for two hours the day before. That night she felt a severe pain in the pelvis, and in the morning she noticed that blood had flowed from the vagina. She was kept in bed and rest was secured by small doses of opium. In spite of this, labor pains set in, and in six hours the second stage had begun. The hemorrhage had been quite steady, but the amount was small, and I did not think it was necessary to hasten the labor or to increase the risk of infection by packing the vagina with gauze. At no time did the child show any signs of approaching danger. Two hours after the second stage began the child was delivered. The position was L. O. I. A. During the third stage the uterus required some stimulation before it contracted satisfactorily, and fifteen minutes later the placenta was delivered by Crede's method. During the third stage the hemorrhage was greater than earlier. Examination of the placenta showed on the maternal side, near the border of the placenta towards the site of rupture of the membranes, a spot 2 cm. wide and 7 cm. long, which was darker than the rest of the placenta. Rupture of the membranes occurred 5 cm. from the edge of the placenta.

The puerperium was uneventful and the child and mother are now both well. In this case there were none of the usual causes, as twins, too short a cord, bag of membranes not rupturing, breech presentation, or the contraction ring mounting to high and lessening the placental site.

PRESENTATION OF THE PORTRAIT OF DR. FESSENDEN NOTT OTIS TO THE ACADEMY OF MEDICINE OF NEW YORK.*

By L. BOLTON BANGS, M.D.,
NEW YORK.

Mr. President and Fellows of the Academy of Medicine:

As I look upon the portraits on these walls I see the faces of men who have contributed to the advancement of medical science and who have aided by their personal labor and devotion the interests of the Academy. They have been deemed worthy to be kept in perpetual remembrance. We have no Westminster Abbey in this country, where the achievements of the honored dead may be brought to mind by bust or slab; and the best that we can do to remind future generations of our own great ones is either to inscribe their names and deeds in a "Hall of Fame" or to place their portraits where many shall be led to ask, "Who is this man; and what did he do to entitle him to this honor?" The other Fellows of this Academy will have no difficulty in answering these questions in regard to Dr. Otis, but, for the sake of the younger ones, out of whose view Dr. Otis has passed, let me give, as well as I can in the short space of time allowed me, an idea of his character and achievements.

Born in 1825 of revolutionary stock—a stock which Americans venerate—he received a liberal education at Union College in this State and a medi-

*Presented at a meeting of the New York Academy of Medicine, April 6, 1905.

cal degree from the New York Medical College, and after an interneship in the old Blackwell's Island Hospital he became surgeon to the United States Mail Steamship Co., or the "Panama Line." Those were the old California days when thousands flocked across the Isthmus of Panama to the gold mines, and he led an arduous but interesting life. His resources were limited according to our ideas, and his inventive genius was often tested by the requirements of peculiar and serious cases. With but few moments of leisure, he found time to write a "History of the Panama Railroad and its Connections," which anyone interested in our canal enterprise would do well to read. It gives a detailed and graphic account of the country between Colon and Panama, with charming descriptions of its flora, and from it one may get a good idea of the obstacles which our engineers will have to overcome. Later, in 1862, he became lecturer on genitourinary subjects in the College of Physicians and Surgeons in this city, and subsequently, 1871, Clinical Professor, a post which he held until 1890, when he was made Professor Emeritus. There was no end to his industry. Besides the lectures which he conscientiously prepared and remodeled from year to year, he made many contributions to societies and journals; carried on an arduous daily practice and wrote books relating to branches of his specialty. His original conceptions of the pathology of syphilis and of the male urethra awakened attention and led to a sharp controversy which he met with courage and with all the force of his legal mind. Believing himself to be right, he wrote with the strength of conviction, and his teachings as to the physiological capacity of the male urethra carried genitourinary surgery forward with a stride and made possible the perfected operation of litholapaxy. He was fertile in invention, and besides the numerous instruments which he gave to the profession there were adaptations, trifles perhaps, in the course of practice which met the necessities of peculiar conditions and which helped to solve difficult problems. As evidence of the esteem in which his scholastic and professional attainments were held by those most competent to judge, he received from his Alma Mater the degree of Master of Arts, and from Columbia University the degree of Doctor of Laws. His social and domestic life was delightful and refined by a simple and enduring faith. Fearless, yet deeply conscientious, he often suffered from a sense of his responsibility, and I have known him to get out of bed in the dead of night, go to the house of a seriously sick patient and walk up and down in the street opposite watching for any commotion within, lest by going in he should give cause for alarm; and one of the causes of his final break up was his devotion to the son of a friend. Had he faults? Who is without them? But faults in a character whose ethics are high, whose general trend is toward righteousness, are but the shadows which make the virtues more resplendent. In a close association of nearly fourteen years he never spoke to me an unkind word and was always kind, generous, and courteous. By placing upon its walls the likeness of such a man, whose example we well may follow, the Academy honors itself; and I have the honor, in the name of his family, to present to it the portrait of Dr. Fessenden N. Otis.

Tricuspid Obstruction.—Joseph M. Patton believes that although tricuspid obstruction is characterized by all authorities as one of the rarest of valvular lesions, it is not of so rare occurrence as some have supposed. There has been noted a remarkable relative frequency of this lesion in the female. The third decade of life shows the greatest number of instances, although certain authorities have declared the lesion to be congenital in the great majority of cases. The congenital form is generally associated with stenosis of the pulmonary artery, defects of the septum, patent foramen ovale, or ductus Botalli, and clinically with marked cyanosis, clubbed fingers, and early death. Rheumatism and chorea play the usual prominent part in the production of this lesion. Gibson believes that it may be caused by other acute diseases than rheumatism, and that chronic valvulitis from over-exertion may also cause it. As to the morbid anatomy of tricuspid obstruction, a more or less funnel-shaped adhesion of the valves is common. The chordæ tendinæ are usually thickened and shortened, and the papillary muscles are retracted. The principal valvular changes may be granulations, vegetations, fibrinous contraction, thickening, and rigidity. There may be considerable deposits of inorganic salts in the tissue of the ring and the base of the valves. The orifice itself may be oval or circular, and may admit the tips of one, two, or three fingers. The ring may be cartilaginous, or of almost bony consistence. The interpretation of the secondary effects of tricuspid obstruction upon the heart, in practically all recorded cases, has been modified by effects due to the associated lesions. It is practically impossible to separate these effects, since mitral lesions, especially obstructive ones, may produce almost identical effects upon the right ventricle and auricle as those resulting from tricuspid lesions. Indeed, the associate lesions are so constant as to be almost part of the pathology of tricuspid obstruction. Out of 154 recorded cases, there was mitral involvement in 138 cases. On account of the associated lesions, the symptoms of tricuspid obstruction must be regarded as equivocal and the diagnosis difficult. Enlargement of the right auricle, with more or less venous stasis, may be regarded as good evidence, especially when associated with a presystolic murmur which can be differentiated from a mitral presystolic murmur. Various authorities have held differing opinions about the chacracteristics of this murmur. A characteristic tricuspid presystolic thrill at the left edge of the sternum that can be differentiated from a mitral thrill must be considered as exceptional. The writer believes that in instances in which a verified diagnosis was based upon the characteristic murmur, the conditions were exceptional and the diagnosis fortunate. Dyspnea, if present, is not so prominent as in some other heart lesions. Susceptibility to cold, a tendency to cyanosis, and possibly venous pulsation are shown. The prognosis of tricuspid obstruction can be approximated only as affected by the associated lesions. The writer then cites the history of a case of this nature which came under his care. The patient, a woman of 24, gave no history of rheumatism. There were double aortic and mitral murmurs. The aortic systolic murmur was unusually loud and rough, and was transmitted over almost the entire front of the chest, being especially marked from the second to the fifth ribs along the right parasternal line. The other murmurs had the usual characteristics. Moderate dilatation of the right auricle and slight tricuspid regurgitation were recognized. The possibility of a tricuspid lesion was considered, but nothing definite was recognized. At autopsy the tricuspid opening was found to be almost round, measuring 1½ by 7 cent. (normal for women 1.5 inch). The upper and inner surfaces of the ring were rough, irregular, and hard. The valves were thick, retracted, and partly adherent at their bases. The physical changes in this heart explained the clinical symptoms, which were those of aortic and mitral disease, and were not at all indicative of tricuspid lesion. There was no hypertrophy of the right auricle, which shows that the tricuspid lesion has no such effect on the auricle as the mitral lesion has on the left auricle. The tricuspid lesion, although of considerable pathological interest, had little bearing on either the clinical history and symptoms or on the physical changes in the heart. In these respects this case only corroborates the majority of those previously recorded.—*The Clinical Review.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, April 29, 1905.

THE NATURE OF HEMOPHILIA.

IN spite of the energy with which numerous observers have pursued their investigations into the nature of this singular affection, but very little actual knowledge has been gained, and although several theories have been advanced, all views as to the etiology are still mere speculations. In a recent number of the *Zeitschrift für klinische Medicin,* H. Sahli of Bern describes observations made in four hemophiliacs who have lately been under his care. The patients belonged to three different families, and inquiries into their genealogy revealed the typical transmission of the disease by the female line to the male descendants. The clinical picture presented by the patients was also the usual one, and determinations of the alkalinity of the blood, the dried serum residue, the freezing point of the serum, and the fibrin content of the blood gave normal results. A relative and absolute diminution in the neutrophilic leucocytes was found and the blood platelets were present in numbers within the limits of health.

In studying the coagulation time of the blood, however, an interesting observation was made which tends to reconcile the discrepancies in the results obtained by various authors. In all cases it was found that the coagulation time was greatly prolonged if the test was made in an interval when the patient was not suffering from any hemorrhage, but on the other hand, blood obtained, even by a separate puncture from another part of the body, at a period when the patient was suffering from some bleeding injury, showed a greatly diminished coagulation time. The fact that hemorrhage persists in spite of this paradoxical increase in clotting power must be ascribed, according to Sahli, to some peculiarity of the injured vessel walls, which in consequence do not furnish adequate amounts of the substances which should exert a local activity in the process of normal fibrin fermentation and clot formation. The nature of these observations is regarded by the author as affording physiological evidence of the participation of the damaged vessel walls in rendering thrombus formation possible, and in hemophilia this activity is either absent or greatly reduced. The reduction in coagulating power during the hemorrhage-free intervals indicates a similar disability, analogous to that of the vessel walls, on the part of the blood cells or the blood-forming organs, and this may form part of a general defect of the body cells hereditarily transmissible by the germ plasm. This assumption also serves to explain the spontaneous or idiopathic internal hemorrhages of hemophiliacs, particularly if with the disordered chemism of the vessel walls there is associated abnormal friability or permeability, and a similar course of reasoning may be applied to the origin of the arthritic manifestations sometimes observed.

Whatever of merit this view may present from the theoretical standpoint, it brings little that is helpful to the question of therapeutics. At present the only general treatment to be considered consists in an attempt to improve the general condition by overfeeding, etc., while for the bleeding, when it occurs, compresses soaked with gelatin solution yielded the best results. Sahli condemns the injection of adrenalin or of gelatin, and says that the internal administration of calcium chloride has no logical foundation. Ferric chloride locally also is not of service. However, the effectiveness of the gelatin compresses may possibly be increased by the addition of adrenalin solution.

ANTITYPHOID INOCULATION.

THE advisory board for the British Army Medical Services has been superintending investigations with regard to Professor Wright's antityphoid serum. To Lieutenant Colonel David Bruce was entrusted the duty of preparing a report on the subject, which report is published in the *Journal of the Royal Army Medical Corps* for February, 1905. Dr. Dodgson also prepared a report founded on the result of investigations carried out at the military hospitals in South Africa. Dr. Dodgson's report is reviewed at length by Colonel Bruce. The conclusions reached were that the general statistics available up to the present are not sufficiently complete or exact to permit of any conclusions being drawn as to the utility of Wright's antityphoid inoculation. Dodgson's statistics are of little value as an aid to the formation of an estimate of the effect of antityphoid inoculation on the incidence of the fever among the troops, owing to the smallness of his figures. His results are also of no practical value in an estimation of the case mortality; but if any conclusion can be drawn from them, it is that the case mortality is not affected by the inoculation. Although the future of antityphoid inoculation does not appear to be very bright, yet in view of the enormous importance of the subject and the possibility, when the method is further developed, of its exerting a practical diminution of the incidence of typhoid fever in armies, the study of this system of prevention should be persevered in. In future, however, the inoculations, if continued, should be carried out under strict supervision and on a properly constituted basis. Colonel Bruce suggests that the subject be brought before the advisory medical board, and he thinks that the best way to collect trustworthy evidence in the future would be to inoculate as nearly as possible 50 per cent. of each regiment or unit proceeding to a station where the disease is endemic. This should be performed by a skilled medical officer at least three months before embarkation. Inoculation in presence of an epidemic, or even after arrival in an endemic area, ought to be discontinued; and the writer also condemns the practice of inoculating troops on board transports.

In general Bruce's conclusions are decidedly adverse to Dr. Wright's antityphoid inoculation method, but the latter and those who are in favor of the method are by no means satisfied that the investigations have been carried out in the best pos-

sible manner. Indeed quite a little war has arisen from the discussion of the subject and there has been an acrimonious debate in the British medical and lay press on the matter. Professor Wright and Dr. W. Bulloch have resigned their seats on the antityphoid committee, as they hold that the further improvement of the process of antityphoid inoculation and the study of the problem of immunity against typhoid fever can be properly carried out only through the agency of a permanent working committee consisting of civilian experts and Royal Army Medical Corps officers.

ACNITIS AND FOLLICLIS.

Acnitis, so named by Barthélemy, is considered by Riehl as distinct from the similar appearing condition known as folliclis. It is identical, however, with the acne telangiectodes of Kaposi. Since it has no etiological relationship with tuberculosis, it must be wholly excluded from the group of tuberculides and tuberculomas. Though the name suggests acne, with origin in sebaceous structures, it is found that the process does not start from the sebaceous glands. The sudoriferous glands are involved in the inflammatory process, and furnish an etiological factor of seeming importance.

Folliclis, on the other hand, once thought by many to be identical with acnitis, with which it has many clinical features in common, has been shown by Alexander in the *Archiv für Dermatologie und Syphilis,* LXX, to be in all probability a tuberculosis. There are two types, one presenting deep-seated nodes associated with tuberculous lesions, and the other showing superficial nodes with diffuse inflammatory infiltrations, or a condition of thrombophlebitis. An embolic origin exists without doubt for both types. It is considered probable that the emboli are formed of tubercle bacilli given off from some tuberculous focus in the body, which become arrested in the smaller arteries of the subcutaneous adipose tissue. Here they set up an endoarteritis or a periarteritis of tuberculous nature.

While no bacilli were found by Alexander and inoculation attempts failed, still from the fact that tuberculin injections caused both local and general reaction the tuberculous nature was assumed. Clinically, folliclis is rare, occurring chiefly in so-called strumous subjects. There are crops of light red macules over the hands, arms, or other parts, gradually changing into deep-seated nodules which later show small vesicopustules upon their summit with exudation and crusting or scaling, especially upon the hands. Minute cicatrices may result from central necrosis and suppuration.

A Sanatorium on Wheels for the Treatment of Tuberculosis.

In a recent number of *The Lancet,* Dr. W. H. Haw, describes a plan of taking a journey in a South African bullock-cart, claiming that in this way all the advantages of sanatorium life can be enjoyed and with a minimum of expense, but a maximum of enjoyment. His idea is to have a team of bullocks which would travel about two miles an hour over ordinary country roads. He describes how the wagon should be constructed, made rain proof, fitted up, etc., and enumerates the items of baggage necessary to journey comfortably. His remarks apply particularly to journeying over the South African veldt. He claims that under the conditions specified, one would obtain fresh air, would be protected from cold winds, rain, and in summer from the heat, could regulate his rest to exactness, could exercise at his will, avoid dust or wear a nasal filter for the dust on the veldt would be bacillus free; could in fact obtain all the advantages of life in a sanatorium without its monotony and depressing influences. While the plan outlined by Dr. Haw is rather attractive, we fear that it is applicable to but few localities, and is in fact a somewhat cumbrous method of leading an outdoor life. Its constant change of scene is perhaps its most attractive feature, for sanatorium life is apt to become monotonous at the best. Moreover, the aggregation of many patients with the same malady is apt to breed a mutual depression and interchange of complaints. Obviously, too, the traveling cart is not to be recommended to the patient with advanced lung disease, high fever, or prostration. Our own mountain regions, especially the lake areas, as the Adirondacks, offer by their waterways much more comfortable methods of changing surroundings than bullock-carts. The ideas of Dr. Haw are, however, carefully worked out and his definite statements will be instructive to anyone contemplating this mode of a frequent change of environment.

Legislation Against Cigarettes.

The anti-cigarette crusade is being vigorously pushed in many of the Middle Western States, Indiana, Nebraska, and Wisconsin having already enacted laws in favor of the reformers. In Indiana the law has been effective about two weeks and a large number of arrests is reported of persons found smoking cigarettes or having the materials for their manufacture in their possession. Penalties are prescribed against any one selling, giving away, or having in his possession cigarettes or cigarette paper, and the punishment is doubled with each infraction of the law. In Wisconsin and Nebraska similar measures have been passed and will become effective on July 1. In the former State the penalties are very severe and range from a fine of $5 to ones of $500 and six months' imprisonment, and to encourage enforcement of the law half the money collected in fines goes to the informants. Bills with the same object in view are pending in Illinois and in Michigan. It is interesting to watch the spread of this cigarette prohibition movement and to speculate on its causes. There is absolutely no reason from the point of view of morality or health why a full grown man should not be allowed to smoke a cigarette as well as a pipe or a cigar, and from the point of view of a nuisance the cigarette smoker is, to say the least, no more objectionable to his non-tobacco-using neighbor than the tobacco chewer. The cigarette is an evil because it tempts many a boy to smoke who would probably abstain until he reached manhood, or might never smoke, if he had to begin, as his father did, with a black cigar or a rank pipe. But that is no reason for abolishing the cigarette. A law forbidding the sale or gift of tobacco to minors would, if enforced, do more to save children from early and injurious indulgence than any possible anti-cigarette legislation.

A Remarkable Bill.

The present session of the Legislature of this State has witnessed the introduction of a bunch of very bad bills designed to affect medical practice, but the most remarkable in its effrontery is one introduced recently in the Senate by a Mr. Carpenter. It is labeled "An Act to Provide for the Treatment of In-

ebriates and Persons Who Are Addicted to the Use of Drugs," but might with greater propriety been called "An Act to Enrich a Private Corporation." The first section provides that when a person is found guilty of being drunk or disorderly or is convicted of any crime which the magistrate has reason to believe was committed while such person was under the influence of alcohol or any drug, said magistrate may direct that the prisoner take the Oppenheimer treatment for alcoholism or drug addiction. Or if the magistrate merely certifies to the warden or keeper of the prison in which the person convicted of crime or of disorderly conduct is detained that such crime or offense was probably committed under the influence of alcohol or a drug, the Oppenheimer Institute shall have the right to inflict its treatment upon the prisoner. Or finally any person confined in any penal or charitable institution in the State may, at his own request, be treated by the Oppenheimer Institute at the public expense. For such treatment, whether administered at the request of an inmate of a prison or charitable institution (which term would probably cover the public hospitals, if not the private ones as well), or without his consent on the mere belief of the committing magistrate that he had broken the law while under the influence of alcohol or some drug, the Oppenheimer corporation shall be entitled to the sum of twenty-five dollars for each case, to be paid by the town or city in which the person was residing at the time his offense or crime was committed. Comment on such an amazing piece of special legislation is entirely superfluous.

Typhoid Fever from Infected Ice-Cream.

Typhoid fever has been traced to various causes, and for long ice-cream has been regarded as a means of conveying this disease. In *The Lancet* some time ago, an account was given by Dr. W. G. Barras of an alarming outbreak of enteric fever which occurred in September last at Govan, Scotland, and which was clearly traced to infected ice-cream. It has been conclusively proven that the disease may be spread by the use of ice and ice-cream by the fact that its microorganism has been cultivated after having been frozen in ice for a very considerable period. There are so many agencies by which typhoid fever may be spread that it behooves the health departments of cities to keep a watchful eye on all suspected sources of infection and means of dissemination. The ice-cream season is fast approaching, and it would be well to exercise vigilance over the methods employed in its manufacture by the horde of peripatetic venders of this popular summer delicacy in New York.

News of the Week.

The Health Board's Fight Against Cerebrospinal Meningitis.—Coincident with the appointment by the Department of Health of a commission of eminent physicians for the investigation of cerebrospinal meningitis, a corps of medical inspectors, five in number, was organized and assigned to the sanitary supervision of the disease in the Borough of Manhattan. These physicians attend to the isolation and quarantine of patients at their homes, order the necessary disinfection of premises and bedding in cases which have recovered, died, or been removed to a hospital, and report as to the sanitary condition of the premises and any violations of the Sanitary Code. They have had the opportunity of observing a large number of cases of the cerebrospinal meningitis, and their services are at the disposal of any physician who may wish assistance in the diagnosis of suspected cases of this disease. A physician trained in such work, has been assigned to the performance of lumbar puncture in these cases, at the request of the attending physician. The Department of Health advises that lumbar puncture be done in all cases where practicable, both as an aid to diagnosis, and in order to obtain more material for bacteriological study and consequent advancement in our knowledge of the disease. Requests for the services of a physician for diagnosis, disinfection, or lumbar puncture should be made direct to the Department of Health, 55th street and 6th avenue (Tel. 1204 Columbus), where they will receive prompt attention.

The Hospital Saturday and Sunday Collections.—The distributing committee of the Hospital Saturday and Sunday Association met a few days ago in Mayor McClellan's office to apportion this year's collection. After deducting $10,000 for gifts to particular hospitals and $6,000 to meet past expenses and as a reserve for future expenses, a remainder of $76,000 was divided among thirty-eight institutions. The following are the chief beneficiaries: Montefiore Home and Hospital, $7,600; Mount Sinai Hospital, $5,059.21; St. Luke's Hospital, $4,370.24; German Hospital, $4,397.80; Roosevelt Hospital, $3,941.31; Nursery and Children's Hospital, $3,879.44; Lebanon Hospital, $3,682.05; Lincoln Hospital and Home, $3,654.30; Hospital for Ruptured and Crippled, $3,569.32.

Need of An Asylum for the Criminal Insane.—At a meeting of the Medical Jurisprudence Society of Philadelphia, held April 18, Dr. J. Hendrie Lloyd read a communication entitled "The Need of an Asylum for the Criminal Insane in Pennsylvania." He pointed out the distinction between the criminal insane and the insane criminal and maintained that the former require special treatment. In the one insanity is the chief factor, in the other criminality. A differentiation might profitably be made between the innocent insane, the criminal insane and the insane criminal, and separate institutions should be provided for each. The criminal insane and insane convicts should not be permitted to associate with the innocent insane, nor should they be treated in the same institution. The insane convict requires and should be given the same prison discipline as that of the penitentiaries. In the State of Pennsylvania there are in asylums, almshouses and penitentiaries 400 criminal insane, a number quite sufficient to warrant the establishment of a separate asylum for their care and treatment.

Excursion from Portland.—A recent letter to a member of the Association from Dr. Kenneth J. Mackenzie, Chairman of the Committee on Arrangements of the American Medical Association, announces that several trips are being planned for members of the American Medical Association attending the annual meeting at Portland in July. One of these is an excursion to Alaska. The committee expects to charter a steamer, which will leave at a convenient date following the meeting. The regular excursion rate is $100 from Seattle or Tacoma and return, but a special rate of $70 for the trip has been secured. The steamer will stop at southeastern Alaska points, including Ketchikan, Wrangel, Douglas Island, Treadwell, Juneau, Skagway, and Sitka. The trip will consume about twelve days and is one of the finest trips in the world. Arrangements have also been made with the Pacific Mail Steamer Company for accommodations for fifty excursionists on the *Korea*, which sails from San Francisco on July 22. The rate from San

Francisco to Honolulu and return will be $110; from San Francisco to Yokohama and return, $240; from San Francisco to Hong Kong and return, $270. The regular rate to Hong Kong is $347. The committee is also planning to give the members of the Association a side trip to the Coast from Portland, which will enable them to see a Pacific Ocean seaside resort, with a run of about one hundred miles on the Columbia by rail or boat.

Cerebrospinal Meningitis.—There were 1,033 deaths from this disease in New York City from January 1 to April 22. In the corresponding period of last year there were 274 deaths from that cause. There were 104 deaths from meningitis last week, a decrease of thirteen from the preceding week.

Health of the Canal Zone.—Secretary Taft has received the report of Col. Gorgas, in charge of the sanitation of the Canal Zone, for the month of March, from Gov. Davis by cable as follows: "Gorgas' health report for March shows steady improvement. End of March employees were about 9,000; sick in hospitals, 153; total deaths, 11. Equals rate 14 per 1,000; favorable anywhere. In the last thirty days to date four cases yellow fever throughout the whole Isthmus, of which one was in Panama. In previous thirty days twelve cases. Each house in Panama has been fumigated; a great many several times."

Increased Powers for Philadelphia Health-Board.—Governor Pennypacker has approved a bill passed by the Legislature, which has just adjourned, granting to those having charge of the public health and sanitation in Philadelphia the power to make rules and regulations governing the care and control of persons suffering from cholera, yellow fever, typhoid fever, typhus fever, scarlet fever, relapsing fever, smallpox, chickenpox, diphtheria, cerebrospinal meningitis, measles, mumps, whooping-cough, tuberculosis, pneumonia, erysipelas, puerperal fever, plague, trachoma, leprosy, tetanus, glanders, hydrophobia and anthrax. To carry out the purposes of the bill Director Martin has formulated a new health code for the city.

American Therapeutic Society.—A meeting of this society will be held at the Hotel Bellevue-Stratford, Philadelphia, on May 4-6, 1905, under the presidency of Dr. Oliver T. Osborne of New Haven. The secretary of the society is Dr. Noble P. Barnes of Washington, and the chairman of the Committee of Arrangements for this meeting, Dr John V. Shoemaker, 1519 Walnut Street, Philadelphia.

Governor Pennypacker Vetoes Bill to Promote Vaccination.—The Governor of Pennsylvania has vetoed a bill passed by the Legislature providing that no warrant be drawn for appropriation to educational, penal, reformatory, charitable, benevolent or eleemosynary institution until the directors shall have made under oath, a statement based upon personal examination that every employee, attendant, patient and inmate is protected against smallpox either by a previous attack of the disease or by vaccination. The Governor hold thats the bill is conceived in an utterly wrong spirit, and that efforts to attain the desired results by the indirect means contemplated by the bill in question, are not to be commended. He does not deny the benefits accruing from vaccination, but he contends that the appropriations have no connection whatever with the subject of vaccination, each being intended to accomplish entirely different ends.

American Association of Pathologists and Bacteriologists.—The annual meeting of this Association was recently held at the Reynolds Club and the Hull Biological Laboratory, the University of Chicago. The officers elected for the ensuing year are: *President,* Dr. James Ewing, New York; *Vice-President,* Dr. A. S. Warthin, Ann Arbor, Mich.; *Secretary,* Dr. H. C. Emit, Boston; *Treasurer,* Dr. N. Hugh Williams, Buffalo; *Member of the National Council,* Dr. F. D. Mallory, Boston.

The American Academy of Opthalmology and Otolaryngology will hold its annual meeting at Buffalo, N. Y., on September 14-16, instead of August 23-25, as previously announced. The president of the Academy is Dr. Hanan W. Loeb of St. Louis, the secretary is Dr. George F. Suker, Everett Building, Akron, Ohio, and the chairman of the committe of arrangements is Dr. Alvin A. Hubbell, 212 Franklin street, Buffalo, N. Y.

Vital Statistics of Philadelphia.—There has been an encouraging decline in the death-rate of the city of Philadelphia for the week ended April 22. Nine new cases of epidemic cerebrospinal meningitis and 57 of pneumonia, were reported. There were 455 deaths from all causes, as compared with 517 for the previous week and 595 for the corresponding week of the preceding year. Sixty deaths were attributed to pulmonary tuberculosis, 45 to nephritis, 39 to heart disease (not including 10 of endocarditis, and 2 of pericarditis), 23 of pneumonia (not including 8 of bronchopneumonia and 6 of congestion of the lungs). Four deaths were ascribed to cerebrospinal meningitis, 3 to meningitis and 6 to tuberculous meningitis.

The International Association of Climatologists will meet in annual session at Portland, Ore., July 11-14, 1905, under the presidency of Dr. John Davis Hartley of Sacramento. The secretary is Mr. Charles H. Peck, 259 William street, New York.

Suit Against a Surgeon Dismissed.—The suit for $20,000 against a prominent ophthalmic surgeon, noticed in our issue of April 1, has been dismissed by the Court, the attorneys for the plaintiff failing to appear when the case was called for trial.

To Prevent Food Adulteration.—Governer Pennypacker of Pennsylvania has signed the bill passed by the Legislature making it a misdemeanor to use more than 1 per cent. of boric acid compounds for the preservation of food-commodities.

Defeat of the Osteopathy Bill.—The bill to license osteopaths to practice in this State on passing a special examination was defeated in the Senate on Tuesday of this week by the narrow margin of two votes. There were twenty-four votes in favor of the bill, but twenty-six were necessary to pass it.

Illinois Sanatorium for the Tuberculous.—The sum to be appropriated for a State sanatorium in Illinois has been reduced by the committee on appropriations from $200,000 to $50,000. The bill, however, providing for the erection of such a sanatorium has been very favorably recommended by the House Committee on Appropriations.

Meningitis in the Navy.—Two deaths from cerebrospinal meningitis are reported among the apprentices at the naval training station at Newport, R. I., and the station has been quarantined.

Slocum Rescuers Honored.—Because many of the victims of the General Slocum catastrophe were of German blood, the Empress of Germany desires to recognize the bravery of the women nurses and employees on North Brother Island who aided in the work of rescue at the time of the disaster last June. Fifty-one diplomas, each signed by the Empress, have been received at the German Consulate and will be presented to those entitled to them.

Knox County (Tenn.) Medical Society.—At the recent meeting of this society the following officers

for the ensuing year were elected: *President,* Dr. Chas. Huff Davis; *Vice-President,* Dr. H. H. McCampbell; *Secretary,* Dr. A. G. Kern; *Treasurer,* Dr. J. A. Q. West; *Custodian,* Dr. Cawood Carmichael.

San Diego Medical Society.—The following were elected as officers of this society for the ensuing year: *President,* Dr. James M. French; *Vice-President,* Dr. W. N. Smart; *Secretary* and *Treasurer,* Dr. Thomas L. Magee; *Delegates to the State Medical Society,* Dr. F. R. Burnham, Dr. Fred Baker; *Alternates,* Dr. James M. French, Dr. Thomas L. Magee.

Tennessee State Medical Society.—At the final session of the annual meeting of this society, recently held at Nashville, it was decided to hold the next meeting at Memphis. Officers were elected as follows: *President,* Dr. Cooper Holtzclaw of Chattanooga; *Secretary,* Dr. Geo. H. Price of Nashville; *Treasurer,* Dr. W. C. Bilbro of Murfreesboro.

Fairfield County (Conn.) Medical Society.—At the 113th annual meeting of this society, held at Bridgeport, the following officers were elected: *President,* Dr. W. J. Tracey of Norwalk; *Vice-President,* Dr. William S. Randall of Shelton; *Secretary,* Dr. Edward M. Smith, Bridgeport; *County Reporter,* Dr. Donald McLean of Stamford; *Board of Censors,* J. F. Schavoir of Stamford; *Fellows to State Society,* Drs. R. L. Higgins of Norwalk and F. L. Smith, F. J. Adams, F. W. Stevens, and H. E. Smyth of Bridgeport.

Whiteside County (Ill.) Medical Society.—Officers elected to serve for the following year are: *President,* Dr. Frank Anthony of Sterling; *Vice-President,* Dr. C. G. Griswold of Fulton; *Secretary,* Dr. C. M. Frye of Rock Falls; *Treasurer,* Dr. J. F. Keefer of Sterling.

A Neurological Society in St. Louis.—A number of physicians of St. Louis met on February 27, 1905, and by vote decided to inaugurate a neurological society, to be called the St. Louis Neurological Society. Those present were Drs. M. A. Bliss, Given Campbell, Chas. G. Chaddock, Frank R. Fry, W. W. Graves, H. W. Hermann, M. W. Hoge, and Sidney D. Schwab. Dr. Fry was chosen President and Dr. Given Campbell, Secretary.

The Late Dr. James Alexander Ferguson.—The following resolutions upon the death of Dr. James Alexander Ferguson were passed at a meeting of the Medical Board of Fordham Hospital, held April 1, 1905:

Whereas the Medical Board of Fordham Hospital has heard with profound sorrow of the death of their colleague and visiting surgeon, Dr. James Alexander Ferguson, which occurred March 7, 1905;

Whereas Dr. James Alexander Ferguson was an esteemed member and for several years President of the Medical Board; he was a kind friend to many, and especially cordial in his relations with the younger members of the profession. Therefore be it

Resolved, That the members of the board hereby express their great grief at the removal of their esteemed colleague by death, and extend their sincere sympathy to the widow, relatives, and friends of the deceased.

Resolved, That a copy of this tribute to the memory of Dr. James Alexander Ferguson shall be spread on the minutes of this board, and a copy thereof be sent to the family and the Board of Trustees of Bellevue and Allied Hospitals.

(Signed) JOHN J. QUIGLEY, M.D., *President.*
THOMAS F. MAGUIRE, M.D., *Secretary.*

Obituary Notes.—Dr. PATRICK J. LYNCH died at his residence, in this city, on April 21. He was born in Virginia, County Cavan, Ireland, in 1828, and came to the United States fifty-five years ago. Taking up the study of medicine, he graduated from the University of the City of New York in 1857, and was chief of clinic to Dr. Valentine Mott for the last seven years of that surgeon's life. He was a member of the American and State Medical Associations, the Academy of Medicine, the County Medical Society, and the Physician's Mutual Aid Association and the Medical Union. Dr. Lynch is survived by a widow and seven children, one of whom, Charles, is a practising physician.

Dr. JOHN HERALD of Kingston, Ontario, died April 12, following a surgical operation. He was born in Scotland in 1855. He graduated at Queen's in 1876, took his M.A. in 1880, and graduated in medicine from the same university in 1884. He settled in Kingston and soon joined the medical staff of the college and was its secretary for years. He was Mayor of Kingston in 1894.

Dr. JOHN H. HINTON of this city died April 26, at the age of seventy-eight years. He was a graduate of the College of Physicians and Surgeons in this city in the class of 1852. He was a member of the New York Academy of Medicine and of the Pathological Society and had served the latter as treasurer for a long succession of years.

Dr. D. NEWLIN STOKES died at Moorestown, N. J., on April 19, at the age of 72 years. He was graduated from Jefferson Medical College in 1854, and he was for many years a member of the Board of Managers of the New Jersey State Hospital for the Insane at Trenton.

Dr. C. V. F. LUDWIG died at his home, in St. Louis, on April 15. He was born in Landau, Germany, and came to this country when quite young with his father, who was also a physician. He was a graduate of the Medical Department of Washington University, St. Louis, in the class of 1858. During the civil war he served as an army surgeon under Gen. Sigel and Gen. Osterhaus. After the war he was an assistant surgeon under Dr. Pope, who founded Pope's Medical College. Later he was curator of O'Fallon dispensary, the first established in the city.

Col. CHARLES SMART, Assistant Surgeon-General, U. S. A., retired, died at St. Augustine, Fla., on April 23. He was born in Scotland in 1841, and was graduated in medicine from the University of Aberdeen in 1862. He came to America immediately upon graduation and during the Civil War served as assistant surgeon in the Sixty-third New York Volunteers, in the Army of the Potomac. He was appointed assistant surgeon in the regular army in the spring of 1864, and in December of the same year was brevetted captain for meritorious services in the field. He was appointed colonel and assistant surgeon-general in 1902. He was the author of several papers on medico-military and sanitary subjects, of a novel, and of a "Handbook for the Hospital Corps."

Dr. WILLIAM B. ULRICH died at his home in Chester, Pa., on April 24, at the age of eighty-four years. He was born in Philadelphia and was graduated from the Philadelphia College of Medicine in 1850. He practised first in Fairview, La., later in Galveston, and removed to Chester in 1867. He was an ex-president of the Pennsylvania State Medical Society.

Dr. HIRAM BARBER of Ossining, N. Y., died April 24, at the age of eighty-five years. He was a graduate of the Albany Medical College, and was for a number of years physician to Sing Sing Prison.

Dr. Samuel Henderson Griffiths, Surgeon U. S. N., died in Washington on April 24. He was appointed assistant surgeon in the navy from Pennsylvania in 1877, passed assistant surgeon in 1880, and surgeon in 1895. He was fleet surgeon of the Atlantic training squadron and was with his command at Guantanamo when taken ill.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PRINCE OF WALES—ECONOMY IN HOSPITAL MANAGEMENT—INTESTINAL DISEASES—COLITIS—AFTER ENTERECTOMIES—ANKYLOSTOMIASIS—SURGERY FOR CONSTIPATION—SATURDAY HOSPITAL FUND—WATERCRESS—OBITUARY

London, April 7, 1905

The Prince of Wales has had to keep to his room for a few days, as he had a trivial operation performed on Monday, but he has continued in such excellent health that no bulletins have been issued. Last week I commented on the Prince's speech at the meeting of the King's fund; his remarks on hospital economy are bearing fruit. Comparative statistics are appearing.

Yesterday the Duke of Abercorn presided at the annual meeting of the West London Hospital, of which he has just become chairman, and commented on the question raised by the Prince. He advocated strict economy, but not at the expense of efficiency, and he thought the two were combined in this hospital—a fact largely due to the harmony between the medical staff and committee. He found that this hospital was more economically managed than, at any rate, thirteen others, and pleaded for further funds.

Yesterday the meeting of the Northwest London Hospital was also held, Dr. Harry Campbell presiding. The report showed that an appeal at the suggestion of Mr. George Herring had brought in £1,527, to which Mr. Herring added £509. The award from the King's fund this year was £500, and it was accompanied by a recommendation to rebuild the hospital. That would probably cost £100,000, and the committee could not see their way to follow the advice. I think they were quite right. There are too many building appeals before the public to leave room for another, and, really, the hospital is doing its work very well. It seems doubtful whether the King's fund committee should encourage the sinking of money in bricks and mortar.

Intestinal diseases have been rather prominent at the societies lately. Dr. Rolleston described under the term pericolitis sinistra some cases which resembled appendicitis, but were situated on the left side. The condition in all cases is one of inflammation of the visceral peritoneum. It may be quite slight, or go on to abscess, and this may burst into the peritoneum, setting up the more expensive general peritonitis. Dr. Rolleston grouped the mild cases affecting the membrane around the descending colon or sigmoid flexure together. They are often spoken of as fecal accumulation or impaction. A second group consisted of cases of localized abscess in connection with perforation of steroral ulcer, either in a false diverticulum or in the wall of the colon, either intra or extra peritoneal, and in either case may extend along the side of the colon, resembling the spread of an appendicular abscess.

Dr. de Haviland Hall was inclined to think the first group connected with a rheumatic diathesis; the second group probably originated in a local cause.

Dr. Caley agreed that many cases were preceded by chronic constipation, but others came on suddenly. Simple colitis was much more common than ulcerative.

Dr. Symes Thompson, in recurrent cases, recommended lubricants for the mucous membrane, *e.g.* vaselin with salol.

Dr. Carver of Torquay followed the paper of Dr. Rolleston at the Medical Society with one on acute infective colitis, dealing with an outbreak in the G. N. Central Hospital, London, in 1902. A number of cases occurred, but in only ten were prolonged records available. Of these, seven were in children—six girls and one boy. The boy and five girls died. The three adults were all females, and one of them recovered. The outset was sudden, violent diarrhea, much blood and mucus passing, anxious expression, coated tongue, tenderness over ascending colon, marked pain on passing motions, temperature slightly raised. In seven or eight days signs of exhaustion set in, and by the tenth or eleventh day feces became more natural and without blood, but the patient gradually sank, and died from the fourteenth to eighteenth day. Afternoons there was always enlargement of the mesenteric glands. The walls of the large intestine were swollen from edema, and scattered over the mucous membrane were numerous hemorrhagic points, about the size of a pin's head; also, there were many shallow ulcers. The bacillus enteritidis was present in the stools, and it was thought the infection was carried by water. The rectum was not affected.

Dr. Hall recalled other epidemics associated with Herroch's purpura and other infections, but he admitted they were not like that described by Dr. Carver.

Dr. C. E. Beevor had had some of the cases under his care and considered the most striking features were the sudden outset and rapid progress to a fatal issue.

Mr. Macnamara had seen a somewhat similar epidemic in Manila, and distinguished it from tropical dysentery.

Mr. Barker read a paper at the clinical society on the condition of the small intestine after extensive enterectomy. Three cases showed that the paresis about an acute obstruction may persist long after the release of the obstruction. A second operation was done two and one-half years, twenty-one months, and two years respectively in these cases. In the two former the bowel above the anastomosis had not returned to its normal size or activity as contrasted with the part below the junction. There was thinning of the proximal portion, and Mr. Barker attributed this weakening not only to distention, but to saturation with toxins. In the third case, the same condition was found, and, in addition, there was adhesion to the sigmoid flexure.

Mr. Malcolm suggested that a break in the peristaltic wave, caused by the cicatrix, might give rise to distention and paresis.

Mr. Spencer remarked on the great extent of these resections, six feet being removed in one case, showing that surgeons need not fear to remove large portions, especially when gangrene had occurred.

Mr. Barker, in his reply, said shock was not increased by extensive resection, and, therefore, enough should be removed to secure healthy tissues for the sutures.

Enterectomy in a new-born child must be very rare. Dr. Kennedy, of the Maternity Charity, was equal to the occasion when a nurse sent him word a child had been born with ineconium coming away from the cord. He found a fistula at the side of the cord, which he slit up longitudinally, exposing a blind finger-like process of intestine, with the fistula in its side. Drawing it out, it was found to be two inches long, and to come from the cecum, and the intestine on each side so narrow he judged it could not maintain the passage, so he excised it and completed the operation by lateral anastomosis, removed the cord and closed the opening. The child was sick for two days, but recovered perfectly. The operation was done without an anesthetic, and "the infant quietly sucked a sugared teat while its intestine was being stitched." Dr. Kennedy has previously recorded in the *British Medical Journal* a radical cure of hernia in a child one day old. Now he is able to add this case, which I think is unique. He thinks it may have been one of persistent Meckel's diverticulum, or possibly an enlarged appendix, as there was no sign of this on the excised cecum.

In addition to the foregoing contributions on intestinal diseases, we have just had, at the Chelsea Clinical Society, a full debate on constipation, extending over two evenings. Space will not permit me to summarize this to-day, but I may mention that Mr. Arbuthnot Lane, who opened the debate, explained the grounds of the operative procedure which he advocates in cases of intractable constipation. He traces many cases to early malnutrition leading to distention and displacement of the large bowel, inflammation and adhesions fixing it. An inflamed and dilated cecum sets up attacks, which may be taken for appendicitis, and this is not relieved by removal. The after history of many operations for so-called appendicitis is exciting much attention, and Mr. Lane explains many failures by the condition indicated. When these exist, and it becomes evident that something beyond wrong treatment must be done, if the patient is to be rescued from a state of steady progress downwards, instead of attempting to free the bowel by dividing the bands and adhesions, he establishes direct continuity between the lower end of the ileum and the large bowel. Some had objected that this would leave the patient the subject of constant diarrhea, but this had not proved to be so. In some of his cases the opposite condition remained for a time.

In these islands ankylostomiasis has been met with for a long time in the Dolcoth mine, in Cornwall, but I hear that it has recently appeared in the Lanark coal-pits. It must have been brought by some foreign workman, for it is common enough in mid-European mines. Dr. Thomas Oliver brought the subject before the Medico-Chirurgical Society last week. It was until lately held that the ankylostoma gained access to the alimentary canal by men eating with unwashed hands or drinking contaminated water; but Loos of Cairo accidentally inoculated himself with a culture, and he has shown that the larva may penetrate the skin and reach the upper part of the small intestines by a

circuitous route. The worm cannot reproduce itself in the human intestine. Ova are constantly passed in the feces.

Dr. Oliver gave an account of continental views and experience. Preventive measures are cleanliness of the workmen, keeping the pits as dry as possible, and a rather low temperature. As to medicaments, aperients and antiseptics are employed, but opinions differ concerning their value. Sometimes Filix mas causes amblyopia. In presence of moisture, at a temperature of 62 to 80 F., the ova are transformed into active larvæ, which can live a long time in the sludge of the mines. In the intestine, the larvæ become sexually-matured worms and attach themselves by their hooklets to the mucous membrane. As they often contain blood, miners' anemia has been attributed to their blood-sucking, but this is disputed, and many think that probably they produce toxins which are absorbed and give rise to the anemia.

Sir P. Manson considered cases are not so rare in this country as generally supposed, and thought that they may become as common as in Germany. Loos had shown that only those embryos that did not pass into the stomach directly gave rise to mature worms. Perhaps the circuitous route through skin, veins, lungs, and gullet conferred immunity from the gastric juice. For prevention, the one thing was to educate the miners. The ovum soon perished without free oxygen, and the Chinese stored excreta in cemented tanks until decomposed, which tended to destroy the ova. The infection was usually multiple, and the only certain diagnosis by microscopic examination of the fecus. He had found three or four doses of thymol, half a drachm each, valuable. The last dose should be given with castor oil and no solvent of thymol should be given at the time. Areca might be tried.

The Epidemiological Society has also had the subject of ankylostomiasis before it, in a paper by Dr. A. E. Boycott. He described the ankylostoma as a parasitic nematoid, differing from other hematozoa in having no intermediate host. Each species is pathogenic to only one species of animal, and at one period only in its saprophytic or larval state. Only one species, *A. duodenale,* is known to attack man in the old world, but a very similar one, *A. americanum,* does so in the Western hemisphere. The eggs are in the jejunum, but are not hatched until they have left the body. They are easily recognized in the feces, hatch in water in about twenty-four hours, and are encapsuled in a week. Only full grown larvæ are infective. In the body perfect reproductive males and females are developed in about five weeks. They are tolerant of heat and cold. Larvæ show vigorous movement for days in the absence of oxygen, the want of which is supposed to prevent the ova from hatching in the intestines. The encapsuled larvæ can survive for months or years at a temperature exceeding 50° F. Dr. Boycott thinks that the anemia is due to toxins; it varies from a 10 per cent. reduction of oxygen capacity of the blood to a degree surely fatal. Some men seem to enjoy immunity from the disease, but they are just as dangerous to others. If miners would abstain from promiscuous defecation the disease might disappear, as it has done from some parts. As an anthelmintic, Dr. Boycott says nothing can approach thymol.

The thirty-first annual meeting of the Hospital Saturday Fund was held on the 1st inst. The receipts for the year were £24,344, the best year this fund has had. In January the committee distributed £22,196 among 190 institutions, being above £1,000 more than in any previous year.

The County Council's medical officer has been visiting the cress beds which supply London. There are 120 of them, varying in size from one-quarter of an acre to forty acres, and it is estimated that they send 1,500 tons of watercress annually to London. The medical officer reports that in most cases there is not much risk in consuming the cress, as it is well washed before eating. But in some beds, he says, the precautions against pollution by sewage or by surface drainage are not sufficient. The council will call the attention of the Local Government Board to the matter.

Lieut.-Col. H. W. A. MacKinnon, of the R.A.M.C., who died last week, aged 63, entered the army in 1865, and served in Egypt in 1882, being slightly wounded at Tel-el-Kebir. He was also in the Burmah campaign of 1885-86. He retired in 1895.

Dr. Thomas Morton, who died on the 27th ult., was a London graduate, with honors. He settled in Kilburn in 1863, and has practiced in that suburb ever since, where he leaves a son, who has for years been his partner. For some months his health has failed, he had sciatica, and subsequently pleurisy. He seemed to be recovering gradually from this, but cardiac failure supervened quite unexpectedly. He held pronounced views on alcohol, was a total abstainer from it, and a promoter of various philanthropic institutions. Among his literary efforts was "Alcohol in Arctic Exploration," an excellent piece of work.

Intelligence reached London on Saturday of the drowning in Lough Rea of Dr. George J. Lough, and his man servant. They were caught in a sudden storm, and the boat was overturned. The occurrence was witnessed from the shore, but assistance was not available. The doctor formerly practiced at St. Leonard's, but had retired. He was only 45 years of age.

Dr. James Alexander of Paignton, Devon, died on the 2d inst., aged 57. He was a Dublin graduate in arts and medicine. He was at one time surgeon to a mining company in Newfoundland, and contributed a paper on the diseases met there to the *Dublin Journal of Medical Science,* in 1878.

Dr. Maurice Griffith Evans, J.P., consulting physician to Brecon Infirmary, died on the 16th inst., aged 74. He was a graduate of King's College, Aberdeen, and practiced for many years at Cardiff. He retired ten or twelve years ago. A few months since he became paralyzed, from which he has died.

OUR PARIS LETTER.

(From Our Special Correspondent.)

LUYS' CYSTOSCOPE WITH DIRECT VISION—METHODS OF ADMINISTERING CHLOROFORM—LOCALIZATION AND EXTRACTION OF PROJECTILES BY RADIOSCOPY—EXTRACTION OF CALCULI FROM THE URETER—RELATIONS OF SYPHILIS TO GENERAL PARALYSIS—ANEMIC CONDITIONS—SURGICAL TREATMENT OF ANTHRAX.

PARIS, March 30, 1905.

At the Société de Chirurgie, Pierre Delbet presented the cystoscope, affording direct vision, which Luys has perfected. It is a simple and ingenious instrument, which makes the examination of the interior of the bladder, male or female, very easy and direct, without the interposition of a prism. The view with this instrument is direct in place of a reflected image. This instrument of Luys is an improvement on that of Kelly. Kelly's method, as is known, is based on the fact that the bladder is filled with air when the patient is placed in the knee-chest position, and the ureter is made to gap. It remains to illuminate the bladder cavity, and it is then ready for inspection. Luys has perfected the method of Kelly. First, instead of placing the patient in the knee-chest position, which is very uncomfortable, he places him in the Trendelenburg position, which is far easier. The instrument is provided with an aspirator tube, so arranged as not to interfere with any maneuvers, but which allows of the aspiration of urine just as it is excreted by the ureters. Thanks to this arrangement, examination or intravesical intervention can be made without interruption. Finally, the light is furnished by a small electric light, a cold lamp, which can in no way injure the bladder, and which gives an illumination much superior to the head mirror employed by Kelly. A movable magnifying glass is so fastened to the instrument that the vesical image is enlarged. The instrument, properly speaking, is composed of a tube 18 cm. in length for a man, and 10 cm. for a woman. In the wall of this tube there is a smaller tube. On the vesical side, this small tube is terminated by an orifice, which opens on the lower and interior part of the larger tube. At the other extremity, the little tube is prolonged by an ajutage, to which is fastened a rubber tube. That is again fastened to an aspirator. This instrument is very easy to use. It allows the insertion into the bladder under the control of the eye, of instruments such as forceps, galvanocautery, and caustic holders, and makes easy a certain number of intravesical interventions. Tuffier has used this instrument and declares that he has never seen the vesical mucosa so clearly and definitely—its coloration, the least roughness, and the form and color of the openings of the ureters—as with this cystoscope of Luys.

Professor Berger discussed the methods of administration of chloroform. While many surgeons favor, in anesthesia by chloroform, the employment of apparatus which regulates the administration of the anesthetic, and which allows air or oxygen to be mixed in certain proportions with the chloroform, Berger believes in the administration of chloroform by the hand of the physician armed only with the classic compress. He does not approve of any apparatus, but thinks that they inspire too much confidence in the anesthetizer, by making him feel that there is no danger when he is using apparatus for this work, and by turning his attention from the observation of physiological phenomena shown by the patient to the oversight of stopcocks, screws, and so on. The best method of administration is the most simple.

Tuffier presented three patients from whom he had extracted bullets. The apparatus by means of which he located and withdrew these bullets from the deep tissues is very simple and is based on the simple radioscope. In

patient, the bullet which gave rise to sensory and motor troubles of the right arm, was located under the subclavicular artery, in the midst of the brachial plexus. In the second patient, the projectile was in the chest, under the left pectoralis major muscle, at the level of the fourth rib. It had given rise to thoracobrachial neuralgia. The third patient had been shot in the left submammary region. The projectile had lodged against the peritoneal surface of the diaphgram.

Picque presented a very interesting observation of a woman of forty-nine years, who for fifteen years had had pain in the lower abdomen. Vaginal touch detected a hard mass in the right vaginal cul-de-sac, and this mass, which was a little irregular, presented at times a sort of calcareous crepitation. The right kidney was increased in size, reaching below the floating ribs, and was painful when examined. Picque diagnosed a calculus of the lower extremity of the ureter with crises of intermittent hydronephrosis. Operation was performed. By an incision parallel to the femoral arch, the peritoneum was stripped off and the ureter was laid bare at the point where it crosses the uterine artery. The calculi were then felt in the interior of the ureter. It was incised longitudinally, and three calculi lying end to end were extracted. They made a mass about 6 cm. long. The ureter was greatly dilated. It was sutured with silk in one plane. Eight days after, the ureteral suture was perfectly firm, and eight days later the patient was entirely well.

Fournier called the attention of the Académie to the pathogenic relations which exist between general paralysis and syphilis. The period by far the most frequent for the manifestation of general paralysis in the course of syphilis is comprised between the tenth and twelfth years. The causes which in syphilitics serve as predisposing agents in the development of general paralysis are, first of all, the insufficiency of antisyphilitic treatment, nervous overstrain, alcoholism, venereal excess and nervous heredity. General paralysis is apt to follow the form of syphilis which is at first benign. It far more rarely follows early malignant syphilis. From observation and statistics, the only guarantee of the patient against the future risks of general paralysis consists in the antisyphilitic treatment, methodically kept up for a long time. This treatment may well have its defects; it is not absolutely positive, but it is the best measure at hand. The treatment ought to be by mercury, and, in general terms, its duration ought to be for two, three, and even four years. It is this long duration of treatment which seems for the syphilitic his best safeguard against cerebral accidents, especially general paralysis.

Pinard presented some considerations concerning the relations of procreation to syphilis. He thinks that specific treatment for six months before generation will enable the father to beget a healthy child. He emphasizes the importance of the syphilitic following the same line of treatment before every act of procreation.

Joffroy and Lancereaux do not believe that general paralysis is a manifestation of syphilis, first, because the anatomical lesion has neither the characteristics nor the evolution of syphilitic changes, and because of the recognized inefficiency of anti-syphilitic treatment in general paralysis. Cornil has concluded by saying that from the anatomical and pathological points of view, cerebral syphilis and general paralysis remain two very distinct maladies. Clinically, however, syphilis is one of the best-known causes of general paralysis, which does not exclude others, such as alcoholism, nervous overstrain, and heredity.

At the Société de l'Internat, Vaquez spoke of the present condition of the subject of anemia. The prognosis of anemia does not depend only upon the cause which produces it, but much more on the condition of the spinal cord to which the modification of the blood bears witness. In the case of plastic anemia, that is to say, with medullary reaction, repeated examinations of the blood alone can teach us the value of the reaction. The appearance of exceptional elements in the blood always indicates a grave prognosis, especially if the number of red corupscles is proportionately low. In the aplastic form, that in which no medullary reaction can be determined, the prognosis has always been fatal. It is in this form that the absence of retractility of the clot is determined, as noted by Hayem. The treatment comprises two principle considerations: To search for the cause of the anemia (unrecognized hemorrhage, intestinal parasites, etc.), and to aid the organism to preserve the blood corpuscles it already has and to make new ones. Arsenic and iron preparations also play a rôle in the treatment. In order to stimulate the hematopoietic functions of the organism, it is necessary to follow other therapeutic methods. Opotherapy, the specific serums, are indicated here. Radiotherapy practised on the epiphyses has given the author excellent results in a case of very grave anemia.

Delaunay operates for anthrax by making a series of incisions. The chief incision runs longitudinally through the length of the infected tissue, and even into the healthy tissue. Perpendicular to this are a number of other incisions. In this way a number of cutaneous flaps are formed that may be curetted thoroughly. Cauterization follows, and the skin cicatrizes marvelously.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

TREATMENT OF FACIAL ATROPHY—EFFECTS OF RADIUM ON NORMAL SKIN—A COALTAR PRODUCT ERUPTION—MODERN CONCEPTIONS OF TUBERCULOSIS—ADRENALIN AND ARTERIOSCLEROSIS.

VIENNA, March 31, 1905

Dr. R. Stegmann of the Rudolph Hospital has demonstrated a case of bilateral facial atrophy, treated by Gersuny, by means of vaselin injections. As four weeks have elapsed since the last injection was made it may be assumed that the present result will be permanent. Photographs of the twenty-four-year-old patient, taken before the operation, represent an uncomely woman, apparently thirty to forty years of age. In discussing the technique, Stegmann called attention to the fact that only vaselin and a mixture of one part of vaselin to four parts of oil were used, the former in regions in which the resulting hard tumor was not undesirable, as in the canine fosse, and the oil mixture in the rest of the face. After absorption of the oil the vaselin remains disseminated through the tissues and gives rise to a new tissue in consistency very like the ordinary subcutaneous fat. He advises against the employment of the hard paraffins, which are difficult to inject, and owing to the high temperature required involve danger of burning. In order to be sure that the injection needle has not entered a blood vessel it is not sufficient merely to wait for the appearance of blood, but suction should be made with the syringe, and only if this is negative can the injection safely be proceeded with. The disease appears not to be as rare as supposed, for within six months five patients have presented themselves for the treatment, which gives such excellent results.

In the course of his observations on radium, already extended over a period of more than a year, Professor Schiff found it desirable to determine the activity of the substance on normal skin. This was all the more necessary, as so far we have no method by which to graduate the dosage except the length of application. For this reason Schiff was anxious to have the substance act as long as possible, and as he did not wish to subject any one else to an injury the degree of which it was impossible to foretell, he applied a capsule containing 55 mg. of radium, of an activity of 200,000, to his own arm. Not until the fifth day did the skin under the capsule begin to show a slight redness, which gradually deepened and finally became cyanotic in color. After some days a thick, hard rusty brown infiltration appeared, resembling the eschar after a burn of the third degree. The circular edge was raised and resembled that of a chancre, while the surrounding tissues were infiltrated and swollen for a distance of about four centimeters. Great pain was present, so that the motility of the hand and forearm was much impeded. This state of affairs persisted for about six days, after which the inflammatory reaction gradually subsided, and five weeks later the skin had returned to a normal condition, except for a slightly adherent scab.

Dr. Loebl presented before the Society of Internal Medicine a thirty-year-old patient with a coaltar product eruption. According to his statements, the patient in the course of the last year had suffered from four sudden attacks of ulceration of the buccal mucous membrane. The affection was characterized by brown discoloration of the lips and tongue, followed by swelling, difficulty in speaking, and the formation of vesicles filled with clear serum. When he came under observation both surfaces of the tongue were covered with confluent ulcers, there was high fever, and the diagnosis of ulcerative stomatitis was made. The etiology at first seemed obscure, as syphilis, tuberculosis, and diabetes could be excluded. The patient stated that soon after the appearance of the symptoms in the mouth a cyanotic, itching edema developed in the forearms and disappeared after a few hours. On examination several shining red wheals were found on the arms, showing that the affection was not limited solely to the mouth. A closer inquiry into the history revealed the fact that about two hours before each attack the patient had taken a dose of one of the coaltar anal?????. The condition was, therefore, a simple drug eruption, or, rather, enanthem, though the abundant literature on this subject records but two cases of such severe involvement of the mouth. The treatment consists in gargling with peroxide of hydrogen.

On the first of March, the Austrian Society for Hygiene held a session for the purpose of discussing regulations for restricting the spread of tuberculosis. Prof. Ferd. Hueppe

of Prague delivered an address on the dangers of infection attending the institutional treatment of the disease, and the measures to be taken to meet this peril. Since the public has become educated to the idea of infection, the presence of the large numbers of tuberculous patients to be found in many summer resorts and watering places has given rise to much popular apprehension; but the people at large, and also many physicians, make the mistake of considering infection and disease as being synonymous, and in the effort to exterminate every bacillus we fall into the error of trying to accomplish too much. Koch's view, that the bacillus with its vital capacities dominates the clinical picture, is no longer tenable. Disease is a process, a variable and not a constant quantity. In order to produce the disease a bacillus must gain entry to the body, but whether it remains there and multiplies or is expelled depends not on the bacillus, but on the body. Our powers of resistance are constantly changing, so that disease is the product of several variable factors depending on (1) the specific organism with its inconstant properties; (2) the susceptibility or resistance of the body; and (3) the circumstances attending the transmission. To-day our conception of tuberculosis is much more far-reaching than formerly. Infection may emanate not only from tubercles, but also from tuberculous infiltration. Laboratory experiments are exceedingly valuable, but their results cannot indiscriminately be applied to the human subject. In the case of the guinea pig, a single tubercle bacillus is sufficient to bring about prompt death of the animal, but for man the conditions are much more complex. Even Galen knew that frequent prolonged contact with sick persons was necessary to reproduce the disease in the healthy, and it is still unknown how many germs are required. If an individual's powers of resistance are sufficiently great to destroy a quantity of bacilli daily, he may go about for years with tuberculosis without suffering from it. Tubercle bacilli are found almost everywhere, and may easily be demonstrated in healthy people. Large numbers are often present in the nasopharynx without doing any damage. In conclusion, Hueppe said that he had been accused of underestimating the importance of the germ, but that this statement was unfounded, for as far back as 1883, he had emphasized this. At the same time, however, he called attention to the significance of susceptibility, which plays as large a rôle as the germ itself. Whereas Koch demands absolute disinfection, Hueppe's standpoint is to fight the bacilli where they are accessible.

Dr. Sturli has reported on experiments made by the intravenous injection of methylaminoacetopyrocatechin, an oxydation product of adrenalin. Adrenalin produces marked changes in the aorta, is a vasoconstrictor, and causes a temporary rise in blood pressure, which is the result of the vasoconstriction. The question whether the drug acts on the smooth muscle or on the endorgans of the vasomotor nerves is still undecided. Sturli presented numerous microscopical preparations which show that methylaminoacetopyrocatechin gives rise to similar changes. The lesions of the aorta consist in thinning of its wall, which may lead to sacculations and aneurysmal dilatations. The elastic tissue of the media undergoes partial degeneration and the nuclei of the contractile elements lose their affinity for stains. The elastic fibers which ordinarily run a wavy course become straight and finally grow thin and friable, and disintegrate. The changes which affect principally the media, and are but slight in the intima, and are hardly comparable to human arteriosclerosis. Probably the smooth muscle cells are directly attacked. That it is not the rise in blood pressure which causes these alterations is evident from the short duration of the former and also by the experiments of Braun, who used amly nitrite to precent the rise in pressure, but still obtained similar lesions. In the discussion which followed, Prof. v. Schötter said that these results had an important bearing on the conception of arteriosclerosis. There is still much confusion in this field and the tendency to call every stiffening of the vessels sclerosis is incorrect. For example, it is wrong to say that syphilis causes arteriosclerosis. Syphilis produces syphilis of the vessels, but this is not necessarily arteriosclerosis. Various factors may give rise to hardenings of the vessel walls which are quite different from a pathological standpoint, and the lesions produced by adrenalin belong among these.

DIFFICULTIES IN MICROSCOPICAL WORK IN SMOKY CITIES.

To the Editor of the Medical Record:

Sir: Would it seem to you possible that on account of the thick obscurity, the cloudy weather, the mysteriously dark and gloomy sky, so often prevailing in Chicago, there would be more difficulty in microscopical work there than in New York City?

I was pursuing most pleasantly my microscopical studies in New York City. I never thought of surroundings only as being just perfect, when my son requested me to visit him and his family in St. Joseph, Mich. While there I thought I would also take the opportunity of visiting the great city of Chicago, which is so wide awake in all its active industries. I brought my microscope and slides, to continue reading nature's book, which, as Harvey says, is open and legible; and I imagined I would soon finish the little book I was writing. But, alas, alas, in Chicago, all during the fall and winter, scarcely a clear, bright day for microscopical work! I was beyond measure grieved. I came to Chicago in October. All the days seemed so dark and gloomy; rain and snow apparently lasting weeks, and dark, cloudy days unnumbered; and, almost all the time, with the thick, dull, gloomy atmosphere. In New York microscopical work went on undisturbed. The days here might be represented by a few days of one week, when they said, "The good weather is here!" But, instead, we had in that week four days of continuous rain—Friday, Saturday, Sunday, and Monday, clearing off Tuesday morning. This was two or three weeks ago, but with such weather I could never have seen or explained the origin and formation of fibroid tumors. We must see things. I made my researches on that subject in New York City, where there was good light, and also a transparent atmosphere. In Chicago!——

After the publication of my article in the Medical Record, September 14, 1901, I consulted the works of many eminent surgeons and pathologists, to see what might be their views. Pozzi, professor of the Faculté de Médecine, Paris, says: "We still know nothing positive about the exciting causes of uterine fibroma." Henry T. Green, in "Pathology and Morbid Anatomy," "Of the etiology of tumors as a class, nothing certain is known." Henry D. Ingraham, professor in the University of Buffalo, "As to the exciting cause, nothing whatever is known." They give no explanation. I was more and more convinced mine was the right theory; and it is more and more confirmed by further investigation.

One thing helps very much in microscopical work, and that is the method of mounting. Canada balsam is used by many great scholars, and in our best colleges. But I have found that mounting in pure glycerin gives a clearer definition, and better results. This was Dr. Charles Heintzman's method. Still the important thing, the necessity for any kind of microscopical work, is a clear, transparent atmosphere. So as to the thick, obscure days we find in Chicago, I determined to see what the colleges said before I ventured to condemn anything in this great western city. I went to one college, asked a bright young professor if the thick, dark atmosphere would interfere with microscopical studies. He unhesitatingly replied: "We are bothered some here by cloudy days, too dark to do without artificial light; too cloudy to do the best microscopical work." These were his exact words. A representative of Rush Medical College said: "It is very difficult some days to see. We need artificial light." He suggested that the cause was the coal dust, burning soft coal. Two or three days after an eminent pathologist of one of the colleges repeated that it was the coal dust. I still could not accept the idea, especially when we see so often an unexpectedly bright, beautiful day after a continuous fog. What becomes of the coal dust? Is not all the fog the result of the surrounding beautiful lakes?

Progress of Medical Science.

Boston Medical and Surgical Journal, April 20, 1905.

A Method of Producing Ether Narcosis by Rectum, with the Report of Forty-One Cases.—J. H. Cunningham and F. H. Lahey review the history of this method of anesthesia. They have devised a special apparatus which they claim overcomes the usual disadvantages of the method. There have been in their series of cases no diarrhea or bloody stools. In seventeen cases ether was taken by mouth, preliminary to the rectal route, while twenty-four were started by rectum. The advantages are the following: But little ether is used; there is no stage of excitement; vomiting seldom occurs; bronchial secretions are absent; there is a comparatively quick ether recovery; the bowels are slightly constipated. They find that unless the bowel is free from feces it is difficult to produce narcosis. A brief summary is given of the anesthesia details in each case of the series, together with an illustration showing the apparatus in action. Full rules are laid down for the preparation of the patient and the administration of the ether.

Serum Treatment in Multiple Infectious Arthritis.—Four cases are reported by E. G. Brackett. His experience would seem to indicate that the only effect of the antistreptococcus serum in such cases is to cut short the

acute stage. Eventually we have the same deformities and stiffness as of old. Naturally, the amount of resultant damage is lessened by cutting short the acute period.

New York Medical Journal, April 22, 1905.

Nasal Obstruction as a Cause of Disorders of Nutrition.—P. Fridenberg calls attention to the part taste and appetite take in digestion, and to the fact that an intact taste sense presupposes a normal micosa. The sense of smell also is important, not only for digestion and appetite, but as a guard against deleterious elements and putrefactive changes. Anosmia may lead to a blunting of taste, cause lack of discrimination in diet, and to the abuse of spices and condiments. Anorexia may be due to deficient aeration alone. Again, the nasal mucus naturally passes backward and is swallowed. Any abnormal intranasal condition preventing this secretion and diminishing it will, therefore, lead to stomach trouble and thus affect nutrition. Nasal obstruction interferes with respiration and interrupts feeding and swallowing. Much air is apt to be gulped into the stomach, and as a result the patient vomits, for breathing can take place only as mouth breathing and that, too, only between the acts of swallowing. As a remote result, mastication is imperfect and there is an imperfect development of the jaw and teeth. Nasal obstruction leads to the accumulation of discharge in the nasopharynx and this is generally swallowed after it is loosened up by hawking. Thus a vicious factor is introduced into the stomach and leads to a chronic catarrhal and fermentative process in that organ. The author closes with an enumeration of the method he has employed for the relief of the faulty conditions referred to.

A Method of Measuring the X-Rays.—The method advocated by M. Franklin is based on the power of the rays to ionize the gases through which they travel. Practically it makes use of an electroscope and with an instrument of the gold leaf pattern, the relative activities of two radiations may be compared with great accuracy and expedition, and if one of them is the standard unit of activity or bears a known ratio to the standard, the value of the other, in terms of the standard, will be readily deducible. It is necessary only to charge the electroscope by applying a rod of vulcanite, sealing wax, resin, or other suitable material, which has been previously electrified by friction, and then to time the transit of the filament under the influence of the rays. The rate of discharge will vary directly as the activity of the radiation. All computation with consequent delay is eliminated, and the whole process need not occupy more than ten or fifteen seconds. The electroscope may be charged and the rays allowed to enter only at the instant when desired during the exposure, by means of a ray proof shutter at the back of the instrument. The author gives illustrations of the instrument he has devised and a formula for recording the results. The charged electroscope is brought to the same distance from the *x*-ray tube as the patient, and, while the tube is running, a shutter in the electroscope is opened and the time in seconds occupied by the filament in transit across a chamber is noted. The number of records is the exact coefficient of energy of the rays. In this way a definite standard is provided.

Medical News, April 22, 1905

Alcohol as Food.—R. H. Chittenden declares that there is no doubt that alcohol, when taken in moderate doses, can be oxidized in the body and its energy made available for the needs of the system. This is not meant to imply a commendation of alcohol for its food value, or to deny that prior to its oxidation it may not exert some harmful physiological effect. Alcohol can be looked on as a food in the sense that it can replace fats and carbonates as a source of energy. But it also causes an increase, and a very notable one, in the output of uric acid through the kidneys. From experiments on man it appears that this excess of uric acid output is not connected in any way with the diuresis which the alcohol produces, *i.e.* it is not due to a simple sweeping of urates already formed and circulating in the blood out of the system. Not only is the uric acid increased, but the purin bases also, and it was noted that the alcohol did not cause the change above referred to when taken without food as with a purin-free diet. The increase of uric acid appearing in the urine, under the influence of alcohol, is not then of endogenous origin, but is unquestionably associated with some change in the rate of oxidation in the liver of uric acid of exogenous origin, or else there is a change in the rate of production of uric acid from the precursors of uric acid contained in the food. Owing, therefore, to the disturbance on the metabolism, alcohol cannot compete as an advantageous food with fats or carbohydrates. Moreover, certain wines seem to exert an effect on metabolism far greater than is accounted for from their percentage of alcohol. This is particularly true of port wine, and hence even moderate indulgence in alcoholic drinks may be attended with greater disturbance of the metabolic phenomena of the body than prevalent ideas would lead us to believe.

What the State of New York Is Doing for the Insane.—F. Petersen gives an instructive account of the various State institutions for the insane, describing them, their methods of administration, etc. Special allusion is made to the central laboratory for the study of psychiatric problems, the first established in this country. Arrangements have been made whereby many of the physicians in the various institutions may come to the laboratory for instruction, a feature which has greatly increased their efficiency. Much more importance now than formerly is attached to the matter of case histories, which as now taken not only present a clear picture of the mental condition of the patients, but record so completely every physical abnormality that they have already become a treasure-house of important data for reference. It is safe to say that there are over 10,000 histories of patients in the books better recorded than ever before put down in asylum annals. The accumulation of such material must become of incalculable value to investigators in psychiatry; but quite as important is the fact that the very work of their preparation is an education to the young men performing the services, stimulating their understanding, improving their powers of observation, and sharpening their scientific judgment. It makes them better physicians, and in so doing directly profits the patients under their care, who must inevitably reap the benefits of better diagnosis and more expert treatment.

American Medicine, April 22, 1905.

Destructive Skin Diseases, Epithelioma, Lupus Vulgaris, and Syphilis.—Henry W. Stelwagon directs attention to the diagnostic value or ulceration, scarring, or both, as a factor in chronic skin diseases, and especially when the disease is of limited area, as it points in an overwhelming majority of cases to either epithelioma, lupus vulgaris, or syphilis; the smallest proportion of such cases belong to lupus. Many of the so-called lupus cases reported in the various journals in the past several years by those unskilled in dermatologic differences, in connection with Röntgen-ray reports, were, if the histories were correct, examples of the rodent ulcer type of epithelioma, and some, examples of the tubercular syphiloderm. In some instances this conclusion was confirmed by the accompanying photographs. Apparently, a diagnosis of syphilis is often only made when a clear or suspicious history is obtainable, or the patient's virtue doubtful, whereas the fact is that women not infrequently contract the disease innocently from their husbands, may have mild or overlooked secondary symptoms; and, further, that cases of extragenital chancres, whose nature may not have been recognized, are not at all uncommon, and the cutaneous disturbances following may be misinterpreted. In epithelioma the best plan of treatment is the removal of the morbid tissue by incision, curet supplemented by caustic application, or by caustic alone, according to the individual case; the treatment to be supplemented by Röntgen-ray exposures. While Röntgen treatment alone will frequently suffice, it is in many instances tedious, and often stops short of complete cure, and except in particular cases should not be advised as the sole method without stating to the patient the probable tediousness and the possibility of stopping short of complete removal. In lupus, the most rapid results may be obtained by the destructive methods mentioned, followed by the Röntgen ray. But Stelwagon believes the Finsen-light treatment, and the treatment by caustic pyrogallol or arsenical salves, followed by the Finsen or Röntgen-ray treatment, to be the most valuable. The Finsen treatment is valuable, but it is expensive, tedious, and its application requires a trained assistant; and in many instances the Röntgen ray will do the same and with much less trouble. In late syphilitic ulcerative or nodular eruptions the ordinary mixed treatment is usually quickly successful, but in some instances, and especially when the eruption is seated about the nose or the palm, the malady is rebellious and inunctions may often be resorted to before the disease yields.

A Study of Homogenized Cultures of Tubercle Bacilli.—Randle C. Rosenberger found in homogeneous cultures of the human tubercle bacillus, the morphology and microchemical reactions but little different from those present in growths upon blood-serum or upon glycerin-agar. In cultures three months old, the individual elements were very long, 10 microns to 12 microns being an average size. Some were thin, others thick; some stained darkly, the remainder stained very faintly. A number contained small, deeply-stained granules, which slightly exceeded the diameter of the organism itself. As many as eight of these granules were observed in a single element. This filamentous character was quite constant, the threads resembling closely those seen in streptothrices. Rosenberger was un-

able to demonstrate motility in any of the cultures examined, even in cultures only four or five days old. Brownian movement was evident in nearly all preparations. Five c.c. of the homogenized bouillon culture inoculated into the peritoneal cavity of a guineapig, produced caseous nodules ranging in size from 5 mm. to 2 mm. Spreads made from these lesions contained numerous beaded, long, acid-fast bacilli.

Typhoid Fever in Relation to the Urban and Rural Population of the United States.—Seneca Egbert shows by reference to the United States Census Reports on Vital Statistics for 1900, and by means of graphic charts illustrating the numerical data of this Report, that typhoid fever is much more prevalent in the rural portions of the country. He attributes this high incidence of the disease to the unsanitary conditions prevalent in the many towns and villages that, being under 8,000 in population, are too small to be classed with the urban, and which, therefore, make up a large part of the so-called rural population. He concludes: (1) Popular education as to the causation and dissemination of typhoid fever and similar maladies is especially important in the localities and districts indicated by the charts. (2) It is the duty of physicians to impress upon their typhoid patients the importance and necessity of disinfection measures, not only during, but also long after, convalescence. (3) The profession should urge improvement, purification, and care of public water supplies, and should induce those depending on private or suspicious sources to protect themselves against the danger of infection. (4) The profession should work for uniform and satisfactory registration laws and methods, as these always reflexly foster improvements in sanitary conditions.

Journal of the American Medical Association, April 22, 1905.

Eyestrain.—Lewis S. Dixon treats of the general subject of eyestrain and its evil effects and discusses the reasons why all persons with imperfect eyes do not suffer alike from reflex disturbances. The main point in the relief of these conditions is rest. It is a mistake to assume that to use glasses too much or to wear glasses seemingly overstrong weakens and impairs the natural power of the eye. Glasses which correct the optical imperfections of the eyes simply remove the abnormal tax on the muscles which results from the imperfect shape of the eyes, remove the constant strain, render the eyes normal, and give them a fair chance to work and rest just as much and under the same conditions as do perfect eyes. The glasses do not do the work the eyes ought to do; they simply correct imperfections and prevent waste of power. When, he says, the fact is realized that congenital and natural variations in the shape of the eyes are the cause, not only of so-called weak eyes, but of a very large part of the nervous frets and weaknesses which mar the ease and comfort of so many lives, it will be considered wise to hunt for errors in the child. None can be found if they do not exist, nor can strain on the nervous system be avoided, if they do exist, by leaving them uncorrected. The child who thus begins early has no strong eye habits to break up, easily learns to accept a full correction, and by wearing glasses a few hours a day at home, keeps out of all trouble, and is not confined to the glasses, for he never gets exhausted and knows how to rest if he is tired. But he should never discard the glasses entirely, for his errors remain as long as do his eyes.

Some Fallacies in the Agglutination Tests, with a Plea for the Employment of a More Uniform Technic.—Oskar Klotz summarizes his article as follows: Without entering into the discussion as to the chemical or physicochemical nature of agglutination and the bearing this has on the differences in the agglutination reaction, and vice versa, I wish to point out that in carrying out these tests we require a greater uniformity in the technic to allow comparisons of the results obtained by different observers. The susceptibility of an organism to agglutinins increases for the first six months from the time it has been isolated from the animal body and grown on artificial media. Inoculations of animals with broth culture will produce in their sera, beside the agglutinins, precipitins whose reaction in broth culture cannot be distinguished from true agglutination, as the organisms are mechanically deposited in the precipitate. Pseudoclumping may be obtained by using emulsions of bacteria is undiluted broth and testing against the above serum. The agglutination of a microorganism varies with the medium in which it is grown, the reaction of that medium, the temperature of incubation, and the number of organisms present in the emulsion. Pseudoclumping may be produced by sudden changes in the temperature and by the addition of certain chemicals. The addition of carbolic acid or of chloroform as preservatives in an immune serum does not interfere with the agglutination reaction. In using the dried blood test, paper having a soluble gloss should be avoided for collecting the blood. In our hands the macroscopic method for determining agglutination has proved the most useful and rapid. A time limit of three hours has been placed on all these reactions.

Laboratory Diagnosis of Smallpox.—R. L. Thompson comments on the difficulties in the early diagnosis of smallpox and suggests the use of laboratory methods. A rapid method of paraffin imbedding recently described by Henke and Zeller is recommended by Thompson as specially available. It consists in using snippings from the lesions by fixation in pure acetone for from three-fourths to one and one-half hours and then directly transferring them to paraffin at 56° C. The subsequent treatment is that of any paraffin material; applying with the dropping bottle successively xylol, absolute alcohol, thin celloidin, 95 per cent. alcohol, and water to the sections and then using the hematoxylin-eosin stain. The whole process requires about three hours, and the specific skin lesions and smallpox bodies can be observed. He considers that by this method fewer mistakes will be made by a microscopist of reasonable skill in smallpox diagnosis than in the ordinary microscopical tumor diagnosis.

The Lancet, April 15, 1905.

A Remarkable Case of Strangulated Hernia.—H. E. Barrett was called to see a man aged 77 years, and found him dead on arrival. Autopsy showed general peritonitis, caused by a strangulated, oblique, inguinal hernia. From a perforation in the bowel protruded a mass looking like feces, but which was found on closer inspection to be a portion of newspaper, apparently carefully folded up to about the size of a domino, but slightly thicker, forming a hard angular mass; this was lying in the strangulated loop of intestine. Just above it there was another rather smaller piece, also folded. They both had a very slight fecal envelope. At the inquest it came out that the deceased had suffered from chornic constipation and it is not improbable that the paper might have been swallowed in the hope of obtaining an action of the bowels. The hernia was an old-standing one. According to the friends, there were no symptoms necessitating medical attendance, except a slight "bellyache" during the night on which the man died.

A Case of Tetanus Successfully Treated with Antitetanic Serum and Curare.—The patient of E. Collins was a boy of 17 years, who had stepped on a rusty nail. Eight days later the initial jaw symptoms were manifested. Three days later the patient was first seen by the author. The wound in the foot had entirely healed, but was excised, rubbed with pure carbolic, and packed. Ten c.c. of serum were injected and chloral and bromide given by the mouth. The notes of the case show that it ran a very obstinate course, and that repeated injections of the serum were necessary. These not proving permanently efficacious, curare was finally given in one-third grain doses, by the needle. It was nearly four weeks before the patient was considered out of danger. The author lays special stress on the importance of freely exposing and removing the area of inoculation as soon as symptoms of tetanus arise. He believes that large daily doses of the serum are called for. He does not believe that curare has any other effect than to diminish the severity of the chronic spasms, which it does probably by a paralysis of the nerve endings.

The Cure of Cancer.—E. Owen declares that the surgeon is never able to claim that he has *cured* cancers. He can never be sure that the widest possible sweep of the knife has removed every cancer germ, "and a cancer germ adrift in the lymphatic stream is like a message thrown out to sea in a bottle; it may be found years afterwards—goodness only knows when and where." A time limit is fallacious. Then years may elapse before the mass of drifting cancer cells is stranded in an ovary or uterus. Treatment is unfortunately not the same as cure, and yet the most effectual treatment is still removal by the knife. Surgery has made great advances by including in the operation the removal of neighboring glands and lymphatics. One case is recorded of a woman of fifty-five years, from whose breast a cancer was removed in 1876. There were several recurrences in the scar, and three years later the auxiliary glands were removed. From this time, twenty-five years ago, she has remained well.

The Relationship Between Dental and Other Diseases.—R. D. Pedley narrates a series of cases in which a dental lesion was found in each instance to be the initial cause of the symptoms. The series includes alveolar abscess, with enlargement of glands; stomatitis, eczema, weakness and improper diet, malnutrition, fretfulness, sinus in the mandible, chorea, nervous affection of the mouth and eyes, general malaise, with nervous tremors and glandular infection. There is no doubt that systemic infection often results from oral bacteria, and at the bottom is a defective state of the teeth. Apart from the special susceptibility which some patients seem to show to bacterial infection, it is evident that a body where vitality is lowered forms the

most prolific soil for their development. The defective dentition which we meet with in daily practice and among the poor, as seen in hospital practice, has the effect, broadly speaking, of lowering the nutrition of the body, and by so doing opening wide channels by which other diseases are only too ready to find their way. We are face to face with the facts that dental disease is of all diseases the most prevalent among civilized communities; that we are as far from touching the cause of this defect as we ever were. We have in our own hands not only the means of alleviating much suffering out of systematic treatment improving the general health, especially of the young, who are in a sense the most important portion of the community.

British Medical Journal, April 15, 1905.

Iron Acetate in the Treatment of Pneumonia.—Herbert J. Robson states that for the last seven years all cases of pneumonia in his practice have been treated by iron acetate and in severe cases by alternate doses of iron acetate and strychnine. This treatment the writer considers particularly useful under the following conditions: Cases of severe bronchopneumonia occurring in infants or children and in catarrhal and lobar pneumonia occurring in debilitated subjects. In cases in which there are not two properly trained nurses for night and day respectively; for by the regular administration of the strychnine through the night as well as through the day, the heart's action is kept up, and the danger of heart failure at the crisis is very much lessened. In that infectious, creeping, and spreading form of pneumonia following influenza the crisis is hastened and favorably modified; the virulence is lessened and the complication of empyema seldom occurs. Even when bronchitis is present, there seldom seems need to order depressing drugs like ipecacuanha, as the iron acetate seems to act as a good expectorant.

The Hepatic Factor in Biliousness.—Francis Hare declares that biliousness from a clinical standpoint has been ascribed to prolonged external heat, to deficiency of physical exercise, to excess of sugar and rich carbohydrate food stuffs, and to excess of meat and nitrogenous food generally. All of these etiological factors tend to cause at least one effect in common, that is, accumulation of glycogen in the liver. Experiments have proved that accumulation of glycogen in the mammalian liver is favored by external heat and physical inactivity. Sugar and other carbohydrates are the chief foods from which liver glycogen is derived. It can also be argued that the absorption of glycogen-forming material is dependent upon the supply of proteid. An ultra-physiological accumulation of glycogen can give rise to all the clinical phenomena of a bilious attack. The liver cell rich in glycogen is large as compared with the cell that contains no glycogen. Glycogenic distention of the liver causes mechanical congestion of the portal venous system behind the liver. From this system the whole of the alimentary mucosa, from the stomach downward to the junction of the skin and mucous membrane at the margin of the anus, will become congested. For the rapid manufacture and discharge of the digestive juices, and for active digestion, a free escape for the blood is as essential as a plentiful supply. In the course of the congestion, the orifice of the common bile duct will probably become blocked; and this will result in the blocking of the pancreatic duct. There will then be no bile or pancreatic juice in the alimentary canal. The result will be a cessation of the processes of digestion and absorption. Clinically, the symptoms will be anorexia, nausea, and vomiting. In some cases the retrohepatic congestion will relieve itself by diarrhea. By these means the glycogenic distention will be relieved, the hepatic obstruction removed, the mechanical stases dispersed, and convalescence established. The whole paroxysms may be regarded as a strike against the absorption of food in excess of the requirements of the organism. Some of the factors which tend to reduce the amount of glycogen in the liver are therapeutic—namely, abstention from food, physical exercise, climate, purgatives, restriction of meat and nitrogenous food stuffs and restriction of carbohydrates. Others are pathological—namely pyrexia and glycosuria. Calomel is probably the best purgative used in biliousness. Pyrexia markedly reduces the amount of hepatic glycogen. Glycosuria has decided inverse relations with biliousness. The management of biliousness by the means just referred to is far simpler in the case of patients who are well nourished. It must be remembered that in some cases it will be found necessary to provide against an excess of fats not less than against an excess of carbohydrates.

Cold Affusion in Hyperpyrexia.—John Haddon describes how some years ago he found that the sudden shock produced by even a tumblerful of cold water in a case of hyperpyrexia relieved the worst symptoms, showing that it is through the nervous system that good is done by the application of cold water, and that it must be applied suddenly to cause shock. The writer tells of using the cold affusion of Currie in a case of scarlet fever in a boy who was unconscious and limp. The mother held him in a tub while the writer poured a pail of cold water over his shoulders. As soon as the water was applied the patient sprang into bed. His temperature was only one degree lower after the affusion, but his pulse was very different, and he was perfectly conscious. His skin also became moist. He had no other treatment and his progress was uninterrupted. There was no sequela.

Death from Cancer Twenty-Two Years After Primary Operation.—A. W. George reports the history of a patient who, at the age of fifty, had the right mamma removed. The axilla was untouched. For seventeen years there was no recurrence. Five years ago a small nodule was discovered just below the scar. This was removed, and microscopic examination showed it to be scirrhous cancer. A little over a year later another nodule was removed. About this time the inner end of the scar became gradually fixed to the chest wall by a deep growth, too firmly fixed for removal. Finally, the skin ulcerated, although this complication had been retarded for a time by the Röntgen rays. The patient finally succumbed to exhaustion, at the age of 72 years. There was at no time any sign of symptom of a secondary new growth. No sedatives were given, as the disease was painless throughout.

Berliner klinische Wochenschrift, April 3, 1905.

Experimental Observations on Renal Dropsy.—Richter describes observations on animals which tend to discredit the prevailing views as to the part played by retained salts, especially sodium chloride, in the production of renal dropsy. Uranium nitrate was found to have the property of inducing in rabbits the picture of acute nephritis, accompanied by transudation of fluid into the serous cavities and edema of the skin. The edema and ascites were, however, dependent on the administration of considerable quantities of water given cojointly with subcutaneous interjections of the uranium salt. When the experiment was repeated with the addition of sodium chloride to the water consumed, the resulting accumulations of fluid were not greater than those accompanying the ingestion of water alone. Experiments with milk and with mineral waters having different percentages of saline constituents all pointed toward the conclusion that it was the amount of fluid and not the presence of dissolved salts which was responsible for the development of the transudates. This point has a great bearing on treatment, since it indicates that in attempting to prevent or to dissipate fluid accumulations in nephritis it is particularly the liquids of the dietary that require careful management. While it is not altogether clear whether or not an increase of fluid in chronic nephritis really overtaxes the heart and leads to danger of muscular insufficiency, the author considers that his experiments have demonstrated that it is not possible to flush the system, and remove waste products in these cases by such a plan of treatment. The fluid taken in, whatever may be its nature, tends only to accumulate and so to increase the danger of dropsy. This holds true both for the conventional milk diet and the mineral cures, and this feature should receive more attention than the sodium chloride content of the food and the osmotic changes dependent on it.

The Disinfection of Ambulances.—George Meyer calls attention to the necessity of properly disinfecting all ambulances or other conveyances used for the transportation of the sick after each trip and before a second patient is admitted. He suggests a suitable plan of construction for ambulances, the interior of which should have a smooth surface, with rounded corners, and without any projecting cleats, etc. The litter should be as simple as possible and consist of canvas stretched over an enameled iron framework. The bearers should wear canvas gowns, which, as well as the litter and all blankets, etc., should be sterilized by steam after every trip. Experiments on the most practicable method of disinfecting the conveyances are in progress.

Münchener medizinische Wochenschrift, April 4, 1905.

Carcinoma and Sarcoma in the Same Patient.—Landau says that so far about twenty cases have been recorded in which heterogeneous malignant growths occurred in the same individual. His own patient was a man of thirty-eight, who came under treatment for symptoms originating in a rectal carcinoma, situated close to the anal margin. He also presented several exostoses and an osteoma of the jaw a number of pigmented moles were scattered over the body, and a firm non-adherent mass could be felt in the right breast. The rectal growth was extirpated by a Kraske operation and was found to be an adenocarcinoma, while several small polypi in the same neighborhood proved to be benign. Four months after discharge the patient returned on account of pain and a rapid increase in size of the mammary tumor, which was now adherent both to the skin and deeper parts. It had also become soft. The mass was

removed and the axilla cleared, the glands being found normal on microscopic examination. The tumor was a fibrosarcoma of the spindle-celled variety. The operation was seven months ago, but there has been no evidence of recurrence of either growth. The author calls attention to the fact that here of a number of tumors of different natures, two suddenly—one shortly after the other—began to grow and assume malignant characteristics, the polyps turning into adenocarcinoma and the fibroma into sarcoma.

Experimental Observations on the Pancreas and on Fat Necrosis.—Hess describes experiments on dogs relative to the production of the lesions of fat necrosis. After various unsuccessful attempts conducted in different ways the typical lesions were finally produced in an animal that had its pancreatic duct rendered patent by the insertion of a permanent glass canula introduced into the papilla through an incision in the duodenum. A short distance lower down, the gut was constricted, but not shut off, by a double silk ligature. Twenty c.c. of olive oil were injected into the duodenum before suturing it, and the abdominal wound was then closed. The dog lived for forty-five hours, and at the autopsy characteristic areas of fat necrosis were found throughout the omentum and mesentery, and in the fat about the bladder. Numerous necrotic patches were present in the pancreas itself, and in the vicinity of the organ. The author draws the conclusion that in some cases of fat necrosis the papilla previously injured and rendered permeable by the passage of biliary or pancreatic calculi permits fatty food material to enter the pancreatic ducts. The substances formed in the splitting up of the fat by the pancreatic juice damage the cells and form the starting point of the lesion. He also suggests that in some cases of chronic indurative pancreatitis the connective tissue growth may represent a process of repair following a previous necrosis originating in the escape of the fat from the intestine.

French and Italian Journals.

Beneficial Effects of the Thyroid-Graft in a Backward Child.—Lannelongue makes this report in the name of Gauthier and Rummer. In referring to the first time that he grafted the thyroid of a sheep under the skin of an infant cretin, afflicted with myxedema, in 1890, he calls attention to the advance that has been made in this line of work since that time, due in great measure to the work of Cristiani. The graft ought to be transferred while it is warm, only a few seconds elapsing between the time of the detachment of the fragment and its insertion under the skin of the patient. Several fragments are grafted at a time. The operative sequelæ are simple and without any complication. The only difficulty in this operation is to find the proper tissue for the graft. It is necessary to find either a young person who has a goitre to be excised, and in whom there is also normal thyroid tissue, and this cannot be found in all goitrous subjects; or one must profit by an operation which is made in the neighboring region of the thyroid which will allow the opportunity of obtaining a flap of the tissue desired. However this may be accomplished, the immediate result has been excellent in a child three years of age, who was almost an idiot. She did not speak, but uttered only inarticulate cries; she could not stand, and she made constant rotary movements with her head and hands. She was not myxedematous. Thyroid tablets had been administered to her in vain. A graft of four small thyroid fragments was made. The effect was very rapid, for a month later the child was walking with confidence, and showed other signs of intelligence. In order to judge of the true value of the results, it will be necessary to wait for a suitable time to elapse. This child was operated on in May, 1904.—*Le Bulletin Médical,* March 22, 1905.

Treatment of Severe Whooping-Cough by Antidiphtheritic Serum.—Passalacqua has had in his practice a certain number of severe cases of whooping-cough, in some of which there were broncho-pulmonary complications. He tried injections of antidiphtheritic serum in seven of these cases, and they all recovered. The action of the serum can generally be noted after the first injection; but in general, three injections are necessary before permanent effects are secured. Improvement is shown by a decrease in the number of, and in the intensity of, the paroxysms. The improvement under this treatment is slower in the case of whooping-cough than it is in diphtheria. In one of these small patients it was not observed until the sixth day. *Revue Française de Médecine et de Chirurgie, March* 13, 1905.

The Cardiac Area in Cured Tuberculous Patients.—Guilleminot declares that while in tuberculous patients in the beginning of the disease the heart is smaller than normal, as has been established by the measurements of Bouchard and Balthazard; on the contrary, in tuberculous patients who have recovered from their lesions, the heart appears to be under normal size. These facts give great importance to the subject of cardiac mensuration in the beginning of tuberculosis, or in the stage just preceding. Not only does this factor become an element in the diagnosis in the sense that a small heart is one of the signs of the evolution of beginning tubercuolsis; but also a favorable prognosis might be made when the heart is found over the normal in size in incipient tuberculosis. These observations complete the work of Sciallero, who has shown that in tuberculosis, recent and malignant, the heart is diminished in volume, while in patients with old benign lesions, the heart is apparently normal.—*La Tribune Médicale,* April 1, 1905.

Nervous Fever and Feigned Fever in Medico-Surgical Affections.—Georges Dircksen concludes that: Hysterical fever may perhaps exist, but in the majority of cases fever is feigned by means of various artifices. The way of making a diagnosis consists in reading the thermometer after being assured that the vagina and rectum not contain irritating substances, and that they are not seat of local inflammation. Often, simultaneously with fever, these malingerers simulate also dyspnea, syncope, hemoptysis, and vomiting—symptoms accompanying diverse organic affections. These are so well assumed that their combination constitutes a syndrome resembling a true illness. This syndrome is almost the same in all malingerers. There also exists in these malingerers a particular psychical state, which is morbid. The will is so affected that they easily submit to a surgical operation or to energetic medical treatment in order that they may remain in the hospital. The malingerers are hysterical, partly abulic, and the pseudo-fever which is noted in them is truly a simulated hysterical fever. Hysterical phenomena are characterized by the fact that they may be made to appear and disappear by suggestion; hysterical fever, then, ought to be provoked by this proceeding; but all of the writer's attempts of this kind, even when repeated, in hysterical subjects, have completely failed.—*Revue Française de Médecine et de Chirurgie,* March 13, 1905.

Studies of the Hypophysis of Castrated Animals.—Fichera has experimented on animals by castrating them, allowing them to live, and later killing them and examining the hypophysis cerebi. In all cases he has found it hypertion of the suprarenal capsule, with the marked hypertrophy occurred, and of what nature was the connection between the pituitary gland and the sexual apparatus. Taking into consideration the hypertrophy with hyperplasia of the hypophysis occurring in thyroidectomy, or when there is a lesion of the thyroid, and that which occurs by extirpation of the suprarenal capsule, with the marked hypertrophy and hyperlasia occasioned by extirpation of the testicle, there becomes evident a marked relation between the functional activity of the various glands of internal secretion.—*La Riforma Medica,* April 1, 1905.

Formalin as a Preservative for Sediments in Urine, Pleuritic Fluid, etc.—Sereni calls our attention to the disadvantages of formalin as a preservative for urine and other fluids, in that, while it preserves the sediments intact, it prevents entirely or retards the reactions that are necessary to carry on some of the other tests used in the examination of these fluids. It also forms a new compound, which, by its predominance in the liquid over the other constituents of the sediment, does not permit them to be seen, and by its own physical characteristics seems to be composed of globules of free fat in the urine. From this it is distinguished only by chemical reaction. It is necessary always to have in mind this source of error in the interpretation of the microscopical findings when this method is made use of.—*La Riforma Medica,* April 1, 1905.

Histological Alterations of the Intestine and Its Permeability to Bacteria in Strangulated Hernia.—G. Del Conte gives us the results of his experiments on dogs, as well as of the careful histological examination of the intestines in ten subjects operated on for hernia. In nine of these cases there was no penetration of bacteria through the intestine by bacteria, as was shown by culture experiments. In one case there was found bacterium coli; but in this case it was demonstrated that there was a fecal fistula resulting from ulceration. His conclusions are as follows: 1. In strangulated hernia the changes in the intestinal coverings does not go on in a systematic way, but since they are caused by hyperemia, they are tumultuous, and may involve at once all the layers of the walls. 2. In general, the longitudinal layer of muscular fibers and the arterial walls are the most resistant. 3. It is not necessary that there should be serious lesions of the mucosa to permit the passage of bacteria through this layer of the intestine; in the muscular layer they find a filter which, as long as it is intact, arrests their progress out of the intestine. 4. The strangulated portion always contains bacteria; the hernial liquid always remains sterile until alterations take place in the muscles which permit of the passage of bacteria.—*Giornale Internazionale delle Scienze Mediche,* March 31, 1905.

Book Reviews.

MEALS MEDICINAL: with "Herbal Simples" (of Edible Parts), Curative Foods from the Cook, in place of Drugs from the Chemist. By W. T. FERNIE, M.D., Author of "Herbal Simples," "Animal Simples," "Kitchen Physic," etc. Bristol: John Wright & Co.; London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd., 1905.

THIS delightful book is appropriately dedicated to "Our 'Little Marys' (playfully named) with the Homage of a Lifetime Spent in Their Service," but it is good (and not too solid) food for our minds as well, and conveys much information, pleasantly told, other than gastronomic or dietetic, respecting the manifold articles, both wet and dry, employed in the sustenance of man. The author has made a lifelong study of foods and treats of them most entertainingly as well as instructively, dealing indeed less with calories and force units than with the historical and literary side of his subject.

The leading motive of the work, the author explains, is to instruct the reader "how to choose meats and drinks which can afford precisely the same remedial elements for effecting cures as medicinal drugs have hitherto been relied upon to bring about. . . . So that a culinary 'Materia Medica' will stand thus competently and agreeably provided, on which dependence can be placed, even with greater trust than on prescribed drugs." We are not prepared, even after reading a large part of the book, to accept the author's conclusion as to the superior medicinal effect of foods over drugs in all cases, but he does show most convincingly that by a proper selection of food we may often dispense with more violent, if not more potent, drugs in the treatment of many chronic ailments. This, of course, is no new truth, but it is one too little appreciated, and it is brought home to us in this quaint work more forcibly, in a way, than in the more formal treatises on dietetics.

The subjects are arranged alphabetically, and under each head the author treats of the source, the mode of preparation, the nutritive and the medicinal value, all told in narrative style with many historical and literary references, which give to the work a charm foreign to formal medical treatises. There is also a therapeutic index of "diseases and minor ailments, with dishes and drinks (of medicinal parts), proper and sufficient for the curative treatment of each malady." The reader who will delve into this book in his moments of relaxation will derive much pleasure while gaining not a little information of a useful sort.

A BOOK ABOUT DOCTORS. By JOHN CORDY JEAFFRESON, Author of "The Real Lord Byron," "The Real Shelley," "A Book about Lawyers," etc. New York, Akron, O., Chicago: The Saalfield Publishing Company, 1904.

THIS is a most entertaining volume of essays, anecdotes, and sketches relating to medical men of note, for the most part English physicians of the seventeenth and eighteenth centuries, to some off-color practitioners and arrant quacks, and to various phases of medical practice. Incidentally the work contains a large amount of material for a systematic history of medicine in Great Britain. Addressing not only a strictly medical, but also a general audience, the author has discreetly omitted from the selection all material, some of it well worthy of preservation in the proper place, which could possibly bring a blush to the cheek of the innocent reader, but what he has seen fit to include is very good and will afford many hours of enjoyment to the tired professional man in need of quiet recreation.

A well known, and not yet superannuated, medical essayist has said that everyone should devote a half-hour before bedtime to the reading of some good book, and the one who would follow this sage advice may well put this book on his shelf of nocturnal literature. The chapters are short and the matter they contain is entertaining, but not of a sort to arouse sleep-chasing thought. Much of the material is familiar but some of it is new, being drawn from manuscript sources never before published. The volume is the fourth of "The Doctor's Recreation Series," the first three of which have already been noticed in these columns, and by its literary style and the interest of its contents well sustains the high character of the series.

CHEMICAL AND MICROSCOPICAL DIAGNOSIS. By FRANCIS CARTER WOOD, M. D., Adjunct Professor of Clinical Pathology, College of Physicians and Surgeons, Columbia University, New York; Pathologist to St. Luke's Hospital, New York. With one hundred and eighty-eight Illustrations in the Text and nine Colored Plates. New York and London: D. Appleton & Company, 1905.

AFTER having passed through the preliminary stage of over exploitation, natural to the early days of every newly developed branch of knowledge, the science of clinical pathology has gravitated to its normal level in the estimation of medical workers. The man behind the microscope no longer even secretly considers the test-tube and the cover slip as the only infallible means of diagnosis, nor does the clinician regard with suspicion information beyond the reach of his own five senses at the bedside. This decrease in over-confidence on the one hand, and of scepticism on the other, has led to the adoption of more rational views as to the function of laboratory methods, and the present volume is devoted to their presentation in a form practically available for every day use by the practitioner as well as by the special worker.

The general impression created by the volume is most pleasing; the mechanical make-up is attractive, the illustrations are numerous and instructive, and the systematic plan of arrangement, together with a very full index, enhances the value of the book as a work of reference, while closer inspection serves only to confirm the favorable opinion produced. The very large amount of material that is now comprised in this department of medicine, together with its allied branches, is covered with the utmost thoroughness, and, though the book is a large one, the style is characterized by inciseness and absence of verbiage. Many tests, methods, and instruments of foreign origin are given, which have as yet received but little attention in this country. Such, for example, are the Sahli hemoglobinometer, Strzyzowski's modification of the Teichmann test, Donogany's spectroscopic test for blood, a convenient method for identifying lead in the urine by electrolysis, a discussion of the recent work on the significance of occult gastric hemorrhages, with the methods for their detection, etc. Perhaps the most conspicuous feature in the volume is the excellence of the plates representing the various blood pictures, which are marvels of execution and reproduction. These are colored in terms of the modern eosin-methylene blue combinations, and it is to be hoped that their appearance will give the quietus to the impossible tri-acid anachronisms still on parade in most books on hematology. Of especial interest, even to the experienced worker, is the series of depictions of ninety different normal and abnormal red and white cells, and the plate showing the phases of the malarial organism. The mosquito cycle of the plasmodium is also figured with unusual fullness, and the sections on filariasis, trypanosomiasis, etc., embody the most recent discoveries in this field. The sections on the serum diagnosis of typhoid and other diseases, as well as those on the precipitin reactions, also contain much that is new. In the section on the urine many recent practical methods are given and a very complete list of reactions for identifying drugs excreted by the kidneys is included. Chapters containing much practical information are those on testing the functional efficiency of the kidneys, on animal inoculation for diagnostic purposes, and on the examination of milk.

It would be easy to continue to select many more points for special commendation, for the book is teeming with originality, but enough has been said to indicate that it is a most practically useful work. No practitioner of medicine, whatever may be his special work, can afford to be without some book of this sort, and the present volume may frankly be recommended as satisfactory.

THE INTESTINAL CATARRHS. Being a Clinical Study of Colitis, Appendicitis, and their Allies; with a Special New Section on Sprue. By EDWARD BLAKE, M.D., Member of the Royal College of Surgeons; Life Assoc. Sanitary Institute, Great Britain; Member French Hygienic Society; Hon. Memb. Michigan Medical Society; Found. Fell. Brit. Gyn. Soc.; West End Medical Referee for Union Assurance Company; Editor of the "Student's Handbook of Comparative Pathology," by Prof. Woods Hutchinson. Author of: "Interchangeable Character of Dermatoses, Neuroses and Arthropathies"; "Dandruff as a Cause of Facial Acne Pustulosa"; "Chemistry of Animal Heat"; "Indications of Disease in the Hand"; "Paludic Pathology"; "Eczema: its Pathology, Bacteriology, and Treatment"; "Lepra Bacillus"; "Arterial Tension." Second Edition. Chicago: W. T. Keener & Co.; London: H. J. Glaisher, 1905.

ALTHOUGH the author calls this volume a second edition, he explains himself in the preface and states that it is neither a reissue nor a fresh impression of his work on Colitis, published a decennium ago. He goes on to say that "it is a genuine new edition, more than double its former size. Every part has been carefully overhauled and corrected to date. Much has been rewritten. The sections on Sprue and on Treatment are now produced for the first time." The volume fairly bristles with new theories and theories which in many instances will not be accepted by the majority of its readers. He claims that colitis is essentially an affection of the skin, *i.e.* the skin is the starting point of the disease. "Of the noninfective forms, throughout their course; and even of some of the latent infective forms, in the earlier stages, this is probably true, without any limitation." The infection he considers secondary. Again, "it is in part because colitis is a descending disease, that the right kidney is the first to be displaced. It is the first to be reached and is therefore the first to suffer." All in all the work makes interesting reading, but one must take many of the author's opinions with considerable reserve.

Society Reports.

MEDICAL SOCIETY OF THE MISSOURI VALLEY.

Semi-Annual Meeting, Held at Kansas City, Mo., March 23 and 24, 1905.

(Special Report to the MEDICAL RECORD.)

Surgical vs. X-Ray Treatment of Rodent Ulcers and Epitheliomata of the Face.—Dr. C. O. THEINHAUS of Milwaukee said that rodent ulcers were nothing but epitheliomata, and that they did not originate from the endothelium. He had been prompted to write this paper by reason of the observation of two cases, treated by the *x*-ray for six months each, without any curative effect. In fact, both showed increase in size. The first patient had suffered eighteen months with an ulcerated growth in the middle of the left cheek. Various caustics had been applied for several months without avail. The *x*-ray had then been used for six months without avail. He presented a cauliflower growth the size of an apple and bleeding on touch. The microscope showed it to be an epithelioma. The parotoid gland region was swollen and apparently involved. The speaker decided first to remove the growth in the cheek and then to examine with the microscope the tissues in the region of the parotoid to prove the presence or absence of malignancy there. The line of incision near the parotoid had shown no malignant tissue. The second patient had suffered for two and a half years from a rodent ulcer near the left nasal bone. Under the use of the *x*-ray the ulcer had increased. He excised the ulcer, treated the wound with the *x*-ray twelve times and then covered the defect by a flap from the forehead. The results had been favorable. Virchow has said that carcinoma was not a neoplasm of permanence. Its cells were decidedly frail and liable to be destroyed by retrogressive metamorphosis. If we had means to produce this metamorphosis at once, and if we could hinder the growth of accessory nodules, the definite healing of the carcinoma would be assured. The *x*-ray had a decided elective influence on the epithelial cells in carcinoma; it checked the division of nuclei and produced degenerative processes with destruction of the cells, but it did not produce retrogressive metamorphosis, nor did it hinder the new growth of accessory nodules. Neither was it possible to measure the degree of quality or of quantity of the rays necessary. The therapeutic employment of the ray had been a dismal failure, possibly by reason of the limit of penetration. Many cases passed into the inoperable period while the *x*-ray was being used. The surgical treatment of rodent ulcer and epitheliomata must be considered the best. After operation, however, the *x*-ray was of great value.

Transverse Ribbon-Shaped Corneal Opacity.—Dr. J. W. SHERER of Kansas City, Mo., read this paper, reporting a case in a man of 72 years, with a negative family history. He had had typhoid fever twenty years ago, with complete recovery. He had been rheumatic indefinitely. Vision had been keen until two years ago, when sight began to grow dim and the eyes felt scratchy. The eyes had never been painful. He walked slowly, with the lids wide open. There had been neither ataxia nor paresis found in the general or ocular musculature. Tension was normal, and the eyes reacted normally to light and consensual tests. The pupils dilated equally under cocaine. The media were clear except the corneæ. Each cornea presented a horizontal, grayish, granular opacity which extended entirely across the cornea and was separated from the limbus on either side by a narrow interval. The band of opacity was 3 mm. wide on the temporal side, 4 mm. wide on the nasal side, and 5 mm. wide over the pupil. Bilateral iridectomy was recommended and declined. The causative factor had probably been the low grade of chronic rheumatism present. Kalt had reported a case in a man who had suffered for years from rheumatism and renal calculi. Treatment should be directed to the diathesis, if one was present. Schiess had reported a case in which recovery had taken place upon a diet of raisins and cider. Kalt had reported a case in which he had removed a superficial opacity, involving the epithelial layer only, with the knife. Transparent epithelium would be developed safely in a few days. Cases of this nature were rare, only 27 having been collected by Manzutto.

Some Points on Suprapubic Cystotomy.—Dr. E. N. WRIGHT of Olney, I. T., read this paper, reporting a case. While attending post-graduate work in New York some years ago, he had seen a surgeon abandon a case of this character for the reason that, upon incision, he had come in contact with the peritoneum, and had felt that the risk to the patient's life was too great to warrant a continuance. In his own case a boy of 6 years had been brought to his office, presenting obscure symptoms. He decided to examine for stone in the bladder and got the ring of stone. He had also been able to feel the stone with his finger in the rectum. Operation had been decided upon at the patient's home, ten miles in the country. It was a cold day and the log house had no window. The gable end was knocked out for light. He found it impossible to use the smallest catheter, but proceeded with the operation. With much blunt dissection, he reached the bladder. An assistant introduced two fingers into the rectum and pushed the stone forward to the pubes. When the bladder incision was made, the stone protruded in part and was easily removed. He felt that he had saved the time needed for inflation of the bladder, and that the holding of the stone forward to the pubes permitted a small incision into the bladder.

Injuries to the Spinal Column.—Dr. CARL E. BLACK of Jacksonville, Ill., read this paper. He said that the rational treatment of spinal injuries presented a very fertile field for surgeons. All the older surgeons and many modern ones urged a "let-alone policy" in these cases. Of late the attitude of many prominent surgeons had changed, but the majority of physicians continued to follow the text-books and the surgeon was not called until much precious time had elapsed, and with it the most favorable time for operation. The literature of the subject was very small in comparison with its importance, and surgery of the spinal column was still in its infancy. The neurologist must take the lead in seeking for positive signs and symptoms by which the extent of cord injury could be determined. He now felt that it was entirely justifiable to operate to learn whether the cord was crushed or only compressed. He had reviewed the literature of 552 cases; of these 261 were operated upon, and 289 were not. Of those operated upon, 49 per cent. recovered; 40 per cent. died. This 49 per cent. of recoveries referred to both life and function. Of the 289 cases not operated upon, only 25 per cent. recovered both life and function; 65 per cent. of these died; 93 of the 552 were cases of dislocation. Reduction was effected either by direct manipulation or by incision; 76 per cent. of these recovered, and yet 72 of the 93 cases suffered a dislocation in the cervical region; 310 of these cases were fracture cases. The 4th, 5th and 6th cervical vertebræ were injured 59 times; 80 out of the 154 dorsal fractures occurred in the 10th, 11th and 12th dorsal vertebr½. Of the 310 fracture cases, 170 were operated upon; 140 were not. Of the former, 44 per cent. recovered and regained their function; 42 per cent. died. Of the 140 unoperated upon, only 27 per cent. recovered and 60 per cent. died. Gunshot injuries of the spine showed still more remarkable results. Of 104 cases, 47 were operated upon, with 42 per cent. recovering, and 57 per cent. dying. Of the 57 cases not operated upon, only 9 per cent. recovered and 80 per cent. died. His own experience and this study had taught that the mortality ought to be greatly reduced, and that there was absolute necessity for early, if not immediate, operative intervention.

Retrodisplacements of the Uterus; a New Method of Suspension.—Dr. O. B. CAMPBELL of St. Joseph, Mo., read this paper. He said that, with the advent of the Alexander-Adams operation in 1884, the contention was between this operation and the use of pessaries. The universal appli-

cation of one or the other of these methods had been urged. The adoption of the pessary as a means of treatment for this condition had passed into almost total disuse. The Alexander operation was also passing, its field being so limited. The permanency of the results of all methods of shortening the round ligaments had been disappointing. Recurrences had been especially numerous among those in whom pregnancy and parturition had subsequently occurred. A study of the method of support afforded by the various uterine ligaments showed that the broad ligaments were the essential suspensory support while all the others tended to maintain the organ in its anteposed position. When the correction of this displacement was attempted by shortening the round ligaments, it was really an effort to transfer to the round ligaments the function of suspension. The recurrences had shown that the round ligaments were incapable of this new function, especially in those cases in which infection and inflammation entered as factors. The consensus of opinion was that the Kelly method of ventrosuspension should not be used. An ideal method of correcting retrodisplacements should conform to the design of Nature and contribute to the suspensive power of the broad ligaments. In the Campbell operation a mesial three-inch abdominal incision was made, exposing the peritoneum. By means of finger dissection, the peritoneum was separated from the overlying deep abdominal fascia back to the internal inguinal ring. Beginning within three centimeters of the mesial line, the peritoneum was incised laterally to the internal inguinal ring. Any needed work might be done upon the adnexa of this side. Mattress catgut sutures were now placed beneath the round ligaments, through both layers of the peritoneum, and through the parietal peritoneum of the opposite side of the lateral incision. Three of these sutures would be required to close the opening in the parietal peritoneum through which the round ligaments had been drawn, thus making it extraperitoneal, except about one inch of its uterine end. The round ligament should now be attached to the overlying deep abdominal fascia by three catgut sutures. The opposite round ligament should be treated in the same way. Thus the uterus became directly suspended by the stronger ends of the round ligaments and also by the anterior lamina of the broad ligaments. This method furnished the most substantial support obtainable in anchoring the uterus, and was applicable in prolapsus as well as in retrodisplacements.

Symposium on Puerperal Fever.—Dr. Robert T. Sloan of Kansas City, Mo., said that now instances of direct infection by physician or nurse were very few, while those of autoinfection had not diminished. A latent gonorrheal infection might become active at the time of labor and extend to the endometrium. An old pus tube, an ovarian abscess, or a pelvic abscess might rupture and initiate a peritoneal inflammation. A benign bacteriemia might give rise to a vigorous sepsis in the susceptible uterus. Pure saprophytes set up putrefactive changes and produce sapremia, and this might be followed by a true toxemia. The common colon bacillus might produce a toxemia. The most common form of puerperal fever would arise in those cases in which there were pronounced pelvic lesions. The bacteria might enter the circulation, producing a true septicemia. This would be a bacteriemia, plus toxemia, with great destruction of the blood. When thrombi in the sinuses became infected and passed into the blood stream, we had a septicopyemia. This would be shown clinically by metastatic abscesses. In making a diagnosis of puerperal fever, typhoid and malarial fevers, influenza, pneumonia, etc., must not be ignored as complications. The characteristics of sapremia would be chills, high fever, nausea and vomiting, and stinking lochia, full of necrotic placental remains and coagula, without pus, but having gas bubbles in the discharge. The uterus would be large and flabby, not very tender. There might also be an infectious endometritis, with a tender uterus and lochia always containing pus. Parametritis and local peritonitis would be ushered in by chills, fever, pain and tenderness, and, later, symptoms of the formation of pus. General peritonitis would present greater abdominal tenderness, rigid abdominal muscles, with the patient in the dorsal position, with thighs flexed. The pulse would be very rapid, the meteorism extreme, the pain intense until all these symptoms would pass away and the patient show that deadly tranquillity, more ominous than the most extreme agony. Septicemia and septicopyemia were differentiated only by the metastatic abscesses found in the latter. In these fevers, if there should be the symptoms of a grave toxemia, with a pulse rate out of harmony with the temperature, if there was pus in the lochia, the diagnosis of true septicopyemia would be a reasonable one.

Dr. R. C. Moore of Omaha, discussing the treatment, said that the prophylaxis of puerperal fever was modern obstetrics, purely and simply. This was the application of surgical asepsis by all means in our power. While this might be easily secured in hospitals, it was next to impossible in private practice among the very poor and ignorant. Among this class he was often compelled to use in emergencies a pad composed of newspapers, the best obtainable dressing. Intravenous injections of bichloride and of formalin had been used, but had not been adopted by the profession. Decinormal salt solution had been used in the same way with good results, respecially if large quantities were used and the emunctories were functionating well. The serum treatment has been highly commended, and as emphatically condemned. The only serum of use in this condition was the antistreptococcic, and this only when the disease was a purely streptococcic invasion. Hysterectomy had been suggested, tried and very wisely abandoned. As to curettage, he felt that the starting point of the infection was in the genital organs; that removal of the cause was the first indication for treatment. When the point of invasion was within the uterus, a thorough curettage should be done and the uterus swabbed out with pure carbolic acid. Drainage by iodoform gauze was advisable. Later, douches of decinormal salt solution were valuable. The internal treatment of puerperal fever could be summed up in two words: eliminate and support. Calomel, followed by sulphate of magnesia, secured elimination. Eight-drop doses of the tincture of veratrum viride every four hours would reduce arterial tension and increase the action of both skin and kidneys. Quinine, two doses of 20 grains each an hour apart, morning and evening, was very useful. Whiskey in small and oft-repeated doses with an easily digested nourishment completed the supporting treatment.

Chorioepithelioma Malignum.—Dr. A. P. Condon of Omaha, Neb., presented this paper, reporting a case of an Indian woman referred to him in early October, 1904. She was 38 years of age, had a good family history, and had had good health until two years ago. Menstruation had always been normal. She had been married twice, and had borne seven children the youngest being four years of age. She had had one abortion in early married life, and another, at the fifth month, two years ago. The placenta had been retained and had been removed promptly, under anesthesia, by finger curettage. She had been in bed ten days, and had flowed off and on ever since. Six months ago she had begun to have pain in the lower abdomen and to lose flesh, dropping from 198 to 125 pounds. She had some nausea and vomiting. Examination showed a hard, irregular, roundish mass extending from the pelvis half way to the umbilicus. The inguinal glands were not enlarged. There was much emaciation and some fever, temperature between 100° and 101°. She coughed continually, expectorating a bloody mucus. Bronchitis was present, but no tubercle bacilli. The urine contained albumin, blood, and casts. The vaginal walls were covered with large, irregular masses from the vulva almost to the cervix. These growths were soft and boggy, and there was a small ulcerated area in the posterior wall of the vagina. All these conditions warranted the diagnosis of chorioepithelioma malignum. Operative procedure was out of the question. The vagina

was cauterized, under anesthesia, and a small piece was excised from the vaginal wall for microscopical examination. This confirmed the diagnosis. Death took place in twenty days. Autopsy showed round nodules of varying size evenly distributed throughout both lungs. The heart was normal. The brain, spinal cord, and abdominal organs showed no involvement. The right ovary was quite large, cystic, and adherent. The uterus was enlarged and its peritoneal surface showed several raised darkened areas. Within the uterus a large, soft, pliable tumor was seen in the left wall; it did not protrude into the canal, this being intact. In the musculature there were numerous small, soft neoplastic areas. The right side of the fundus was scarcely invaded. The bladder, rectum, pelvic glands, and left broad ligament were free; the right broad ligament was adherent to the tube and ovary, and contained soft nodular masses. The vaginal walls were filled with growths. Sanger reported the first case in 1888. Opinions then differed, and still differ, as to whether it was of maternal or fetal origin. It was still undecided as to what changes occurred in the maternal part which allowed the cells to become malignant. It usually developed upon the placental site. This case was the twenty-second to occur remote from placental implantation. A benign form of this disease was found; it resembles a polyp and might become malignant. Malignant chorioma had been found also in the testicle of the male and in the virgin female. Probably 50 per cent. developed after hydatidiform mole. Whenever a mole had degenerated into malignant chorioma it had been found that there had been an invasion of the stroma of the villi. Metastases occurred in 70 per cent. of cases. To date, about 142 cases had been reported. Hemorrhage was one of the earliest symptoms, and the predominating one. This was the most malignant of uterine tumors. Whenever the scrapings in a case of chronic hemorrhage of the uterus showed malignancy, this disease should be suspected and hysterectomy was imperative.

Renal Affections Simulating Abdominal and Pelvic Diseases.—Dr. J. Block of Kansas City, Mo., said that the simulation of a lesion, or the mimicry of one malady by another, always afforded a profitable subject for discussion. Seldom could the mimic counterfeit every feature of the genuine. He reported a case in which the patient had been found suffering from severe and increasing pain, especially near the navel. The abdomen was tympanitic and the constipation obstinate. The pulse was rapid and slight fever was present, as was occasional vomiting, with continuous nausea. Intestinal obstruction was suspected. When he was seen by the writer, three days later, there had been no fecal vomiting. Plumbism and strangulated hernia were excluded. With the pain and tenderness on the left side, further investigation was demanded. The urine was examined. An abundance of uric acid crystals and a few red corpuscles showed that a renal reflex had selected the alimentary tract to display one of its vagaries. He had met a similar case in a very large man for whom a cholecystotomy with drainage had secured no relief. Urinary examination showed the same red cells and again located the real trouble in the kidneys. A third case presented elevation of temperature, a pulse full and frequent, a tympanitic abdomen, and pain in the right lower quadrant; there was also rigidity of the right rectus. Urinary examination showed the red cells as in the other case. In the absence of the writer, a recurrence led to the diagnosis of appendicitis, but an operation was done with negative findings. The urine was always charged with red cells, and leucocytes were now present in abundance. Cystoscopy disclosed a cystitis. A fourth case was that of a woman after an induced abortion. There had been hemorrhage for over three weeks, uterine pain, temperature at 103°, rapid pulse, chills and sweats, pain in the pelvis and in the right lower quadrant, with pressure symptoms in the bladder. A pus focus near the right tube and ovary was suspected. The uterine discharge was not malodorous. The kidney was very tender, as was the ureter. The urine was loaded with pus, though no catheter had been used. The diagnosis of a septic cystopyelitis was made and the conditions relieved upon proper treatment. He had also met with a host of renal cases with all the subjective symptoms referred to the bladder. He recalled three cases in which he had operated for renal tuberculosis, and yet all the symptoms and treatment of years had been directed to the bladder. A faulty interpretation was always easy, and the relations of the gall-bladder and biliary passages to the right kidney, of the ureter to the appendix, as well as to the appendages and bladder, must never be ignored. The centrifuge and microscope were always at command and should be used.

Anesthetics.—Dr. Cora Greene-Wilson of Kansas City, Mo., said that her address was a plea for the anesthetic specialist. She was much gratified to know that the trained anesthetist was more generally employed. It was formerly thought that any physician could give an anesthetic, and the administration of the anesthetic was entrusted as a sort of placebo to the doctor who brought an operative case to the surgeon. Surgeons were beginning to realize that the anesthetist was more responsible during the operation than was the surgeon. The desired skill in anesthesia could only be acquired by constant practice, and even then best by those specially endowed. She pleaded for complete equality, ethical and professional, between the surgeon and the anesthetist. When the patient was thus informed of the dignity and importance of the anesthetist, he would not object to paying a proper fee. Dr. Alice Magaw, who had administered anesthetics 12,000 times for the Mayo brothers, without a death, had properly said that the administrator of any anesthetic was responsible for the results of the narcosis. As to the anesthetic to be employed, she said that the use of ether was steadily gaining ground, while chloroform was losing. She agreed with Dr. Mellish, who recently wrote that the immediate safety during the administration was so overwhelmingly in favor of ether that those who held to the contrary could not be fully acquainted with the fact, and there were few contraindications to the use of ether. She also agreed with Jacoby of New Orleans that chloroform was more dangerous than ether; that ether was a cardiac stimulant, and that Willy Meyer's experiments had proved that there was more danger from kidney complications in the use of chloroform than in that of ether. She said that Israel of Berlin, an authority on surgery of the kidney, used ether entirely, and that the Mayo brothers used ether almost exclusively. Poncet had administered ether 29,000 times without a death. The chief objections to the use of ether had been the unpleasantness of the old cone method, the postoperative vomiting, and the supposed irritating effect upon the lungs and kidneys. She agreed with Jacquet that chloroform and ether were identical in their method of producing anesthesia, but differed in the secondary results produced. The former depressed the heart and respiration, and lowered blood pressure. Ether did not do this until a toxic dose was reached. Prolonged anesthesia was better borne under ether. Chloroform was very treacherous and killed very quickly, without warning. An overdose was much more easily given than one of ether.

The Treatment of Inguinal Hernia.—Dr. Prince E. Sawyer of Sioux City, Iowa, said that, since nearly 10 per cent. of all people suffered from hernia, and since 85 per cent. of all hernias were inguinal, the subject should elicit keen interest and sharp discussion. The first truss was applied by Campier in 1785. At present, trusses had fallen into disfavor. Radical operations for hernia had been done as long ago as the time of Celsus, but the operations fell into disfavor, by reason of the high mortality, and did not come again into favor until early in the nineteenth century. In 1871 the cure of hernia through an open wound was taken up, and had shown marked success. Nearly all of these operations had one end in view—the obliteration of the sac and the repair of the break in the muscle wall. The transplantation of the cord

was at one time the great question. It was not now so regarded. We should confine ourselves to one method of dealing with the cord. The care of the sac was of equal importance with the suture of the muscular structures. When the sac was found to be small, it should be transfixed; if large, it was much safer to suture it. Tinker's method was a very good one. He used a long ligature, whether he sutured or ligated the sac; upon both ends threaded needles were placed, and the suture was carried well up beyond the border of the internal oblique, thus transfixing the muscle from within downward. Upon tying this ligature, the sac would be drawn up behind a solid wall of muscle. The suture of muscle should not be done until the wound was perfectly dry. He regarded highly the use of a plaster-of-Paris spica, and detention in bed for at least three weeks.

Uterine Displacements.—Dr. W. O. Henry of Omaha, Neb., said that the natural position of the normal unimpregnated uterus was suspension between the bladder and rectum, the cervix projecting through the vaginal vault toward and to within about two inches of the vaginal orifice, while the body of the uterus curved slightly forward. He believed that any marked departure from the above position was a displacement and that it would almost certainly, sooner or later, give rise to positive pathological conditions in the pelvis, or produce more or less serious reflex nervous disturbances. He was of the opinion that it was a safe and sane principle to teach that all displacements should be corrected by whatever means were necessary, unless such correction was more dangerous to the life and health of the patient than the displacement. He felt that most uterine displacements, aside from descent of the uterus, could be corrected early by a pessary, and he therefore taught that the general practitioner should be encouraged to recognize these and to apply the proper pessary as early as possible. He thought that no one operation would ever be devised which could apply to all displacements. He was of the opinion that the Alexander operation was applicable to all cases in which it was reasonably certain that there was no need to open the abdomen, and in which the round ligaments were strong enough, when shortened, to afford proper support. In his judgment, the ideal operation for all other retrodisplacements would be the attachment of the vesicouterine ligaments and the base of the bladder higher upon the anterior uterine surface, after suitable scarification. He believed that the hard rubber ring pessary, the McIntosh, and the Cutter had a field of usefulness for uterine prolapse. He knew that they could not cure, and could not take the place of a well-directed operation, but they could be worn permanently with comparative satisfaction. He also urged strongly that pelvic disturbances were often the important factors in cases of insanity among women, and when they were corrected, the mental condition was easily cured.

Case of Choroiditis, Probably Due to Necrosing Ethmoiditis.—Dr. W. W. Bulette of Pueblo, Colo., read this paper, reporting a case of a woman of 28 years, with good family and personal history. There was no evidence of syphilis. About three years ago, in connection with the grip, she suffered from great pain over the brows and back of the eyes; the nose was stopped up for several days and then the left nostril discharged freely for several weeks. One year later she began to notice flashes of light before the eyes, and would see rings around a lighted lamp or an electric light. These were more marked when she sat in a dark room and looked at a distant light. The vision failed so much that she gave up sewing and reading. Treatment by an oculist for two and one-half years was without apparent benefit. The media were clear. A small patch of choroidal atrophy was found in each macular region. Diagnosis was made of central choroiditis. Examination of the nose showed the turbinates hypertrophied and flabby, with large fibrous masses in each vault adherent to the sphenoid and to the middle turbinals, and pressing against the septum. The tissues everywhere were excessively tender; the mucous membrane over the ethmoid region felt rough and grating, and deep pressure caused sharp pain in the left eye-ball. Turning of the head caused pus to emerge from under the middle turbinate. The above conditions led to the diagnosis given. Dr. Jackson of Denver corroborated the diagnosis, and expressed the opinion that the ethmoid disease was the probable cause of the eye lesion. He suggested a trial of mercury and potassium iodide. She could not take the iodide and the mercury was used, alternating with hydriodic acid. The fibrous growths were removed from the nares, and the anterior ethmoid cells opened. Vision improved after the treatment of the nasal obstruction and the necrosing ethmoiditis.

Drainage in Acute Diffuse Septic Peritonitis.—Dr. Van Buren Knott of Sioux City, Iowa, said that the term used referred to an acute septic inflammation of the peritoneum so widespread as apparently to involve its entire surface, one accompanied by marked changes in the appearance of the membrane and in the quantity and quality of its fluid contents. This variety was usually due to perforation of some of the hollow viscera, with extravasation of septic material. The rapidity of the process depended upon the nature of the infecting medium and upon the point at which it was released. Perforation of the stomach or duodenum was followed more rapidly by symptoms than a perforation in the pelvic portion, because gravity quickly carried the infection across the entire cavity. In this class, the peritoneum was found deeply congested, some portions lusterless, and some with a slight luster. Patches of fibrin and slight adhesions were seen. The fluid seen appeared at times as pus, at other times thin and greenish, or, when in limited quantity, brown. In some cases the entire cavity seemed fairly well filled; in others, fluid would be found only in the fossæ or in the cul-de-sac. Previous to 1900, a mortality rate approaching 100 per cent. was viewed with dismay, but surgeons continued to operate with the best light at their command. Within a short period such various measures of cleansing the peritoneum as by evisceration and dry sponging, by dry sponging alone, by copious irrigation of the entire sac, by continuous irrigation, by drainage of the cavity into the intestine, by capillary drainage, by glass or hard rubber drainage tubes, by counter-openings in the loin and flank or in the male perineum, by vaginal drainage, and, lastly, by raising the foot of the bed and flooding the diaphragmatic area of the peritoneum, filling the already choking lymphatics of the sufferer, had been in turn adopted. The variety of methods portrayed the unsettled and dissatisfied state of the surgical mind. In 1900 Dr. George Ryerson Fowler of Brooklyn published an article describing postural postoperative treatment of diffuse septic peritonitis. He reported nine consecutive recoveries. He took the position that absorption occurred most rapidly from the diaphragmatic peritoneum, and less and less rapidly as one descended toward the pelvis. Ever since, the speaker had followed these teachings and had persistently elevated the head and trunk, thereby draining the high and extremely dangerous area above named into the lower and safer area beneath. He used this method first in December, 1902. Since that time he had treated nineteen cases and lost but two. These had a varying origin, either appendicular, duodenal perforation, rupture of the gall bladder or of a pus tube or of an ovarian cyst, or arising after some operative procedure. He believed that the incision in these operations should be in the median line and ample. He then located the source of the infection and made as thorough repair as possible. He then made a two-inch incision in the median line, just above the symphysis, and introduced a large rubber tube, one to one and a half inches in diameter, split from end to end and carrying a gauze wick which was passed to the bottom of the pelvis. In women he opened Douglas' cul-de-sac and carried this tube, without the gauze wick, through the cul-de-sac into the vagina. He washed out the abdominal cavity with gallons of hot salt solution, and then closed the upper incision rapidly, filling

the abdominal cavity with the solution just before tying the last suture. He left the lower wound open, and, in men, introduced an additional similar tube without the wick alongside the other to the bottom of the pelvis. He then raised the patient to the sitting posture and placed him in a bed the head of which was raised from 24 to 30 inches above the floor. In males, as the drainage becomes scanty, he pumped out the fluid in the lower pelvis every two hours through the plain tube.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 6, 1905.

DR. CHARLES L. DANA IN THE CHAIR.

Presentation of the Portrait of the Late Dr. Fessenden N. Otis, Donated by the Family of the Deceased.—Dr. L. BOLTON BANGS made the presentation address. (See page 657.)

Treatment of Fracture of the Neck of the Femur Designed to Improve Functional Results by Correction of Deformity and by Protection During the Period of Repair.

—Dr. ROYAL WHITMAN, who read this paper, said that the general impression was that in these fractures the prognosis was always unfavorable, in many instances the injury soon proving fatal, and in all the functions of the limbs being permanently impaired. It was a popular misapprehension that classed these fractures as an almost exclusive attribute of old age, as it was far from common even in childhood and might occur in middle life under the same slight provocation as in the aged. The danger of treating these cases had been greatly exaggerated. In 241 cases treated in three consecutive years at Bellevue Hospital there were but three deaths—one within twenty-four hours after admission and two from alcoholism and nephritis. In regard to the questions as to whether the failures in those cases in which treatment had been applied were due to anatomical peculiarities of the injured part that make it an exception among fractures or whether the treatment had been exceptionally inefficient, he said the first question was only one of conjecture, but the second admitted of demonstration. He said that in the typical treatment the use of the lateral splint, in the absence of anteroposterior support, could not fix the fragments, nor was the traction force, ten pounds, as usually employed sufficient ordinarily to reduce or to control the deformity. In the treatment of less important fractures accurate adjustment of the fragments was essential, the character of the support being subordinate. For this automatic adjustment we depended upon traction, which was inefficient if light and uncomfortable, and difficult to maintain if heavy. It might be said that treatment was perfunctory because prognosis was bad, and that prognosis was bad because the treatment was ineffective. He said that we should consider the treatment of fracture of the neck of the femur from the mechanical standpoint, and then take into account the modifications that age, weakness, or other circumstances might necessitate. In cases of impacted fracture the abduction of the thigh was checked by accommodative muscular contraction within the range that the deformity permitted, but when this was overcome it was limited by contact of the deformed neck with the upper border of the acetabulum. If the patient was anesthetized one might by means of the leverage of the extended limb and the fulcrum formed by the upper border of the acetabulum, overcome this restriction by forcible abduction, which must straighten or elevate the neck, provided complete consolidation had not taken place. Traction on the limb and downward pressure on the projecting trochanter during the maneuver might still further aid in restoring the normal contour. If the limb was fixed in this attitude of normal abduction there should be no danger of non-union, but repair should proceed in a more normal manner than if the deformity was allowed to persist. A certain proportion of cases passing for fracture of the neck of the femur were due to fissure or other distortion in the neighborhood of the trochanters permitting depression of the neck. For this class of cases, in which we might include sub-trochanteric fractures, forcible abduction and direct traction under anesthesia should be equally efficacious. As the reduction of deformity of incomplete fracture was quite opposed to accepted teaching, he thought it ought to be stated that it was the method of reduction and fixation that made it feasible. This method which made it possible to reduce the deformity without separating the fragments was as follows: The patient, being anesthetized, was placed upon a box seven inches in height and of sufficient size to support the trunk. The pelvis rested upon the sacral support of the Lorenz model, and the extended limbs were held by assistants. The limb on the fractured side was gently abducted until the normal resistance was encountered, then under traction, the joint being supported by the hands of the operator, the limb was slowly abducted to the normal limit (45°). The pelvis was prevented from tilting by simultaneously abducting the sound limb to the same degree. In this attitude the plaster support was applied. Care should be exercised in the selection of cases. If the fracture was complete the same method might be employed to appose the fragments. In intracapsular fracture one should first flex the thigh somewhat, as this would reduce the distortion due to upward and forward displacement of the proximal fragment of the neck. This flexion might also serve to disengage the iliopsoas muscle if it were interposed between the fragments. The outward rotation was then corrected, and finally the limb was drawn down by direct traction to its normal length as proved by measurement, and abducted in the manner described, downward and inward pressure being exerted meanwhile upon the trochanter. The attitude of complete abduction had the advantages of exercising direct traction upon the capsule, disengaging folds of ligament or muscle that might be interposed between the fragments, and as the capsule was attached to each fragment, it would serve to correct malposition of the inner fragment and to bring the two into contact; it would also relax the abductor group of pelvitrochanteric muscles and so change the direction of the iliopsoas muscle that its contraction would tend to appose the fragments. In the treatment of children and young adults he had employed the long spica extending from the mammary line to the toes, but in older subjects it was of advantage to use a less comprehensive support, and in recent cases he had applied it to embrace the pelvis only. This form of support, a slight modification of the Lorenz, had to be closely fitted about the pelvis, particularly above the trochanter and behind the articulation. It should be wide enough to completely cover and enclose the buttock. If there was a tendency to upward displacement of the opposite side it could be prevented by a wide, firm perineal band attached to buckles hooked over the front and back of the support, so that the band passing between the limbs diverged to cover the tuberosity of the ischium. If the shortening had been completely reduced a traction weight of ten pounds should be ample to prevent displacement. In applying the plaster bandage a skin-fitting covering of seamless shirting with its friction bandage was first drawn over the body and limb and all bony prominences protected by coverings of double canton flannel applied firmly and smoothly. When the plaster was trimmed care should be taken to round the edges and turn them slightly away from the skin. In ordinary cases the plaster bandage was retained for about eight weeks, when it could be removed to permit massage and active and passive movement. Full function should not be permitted for many months. In selected cases which require the open operation he thought the joint might be most conveniently opened by an anterolateral incision on the outer side of the tensor vaginæ femoris muscle. The capsule was then incised in the line of the neck, or more widely if necessary. A long, sharp drill might be pushed through the trochanter and the neck into

the inner fragment, the outer end being driven beneath the skin to guard against infection. The advantage of the abducted position in apposing the fragments was demonstrable, and the limb was fixed at the proper angle by a plaster bandage. The after-treatment was the same as in non-operative cases. In a large class of patients in which treatment had been ineffective and in which the open operation was contraindicated, it was advisable to force the upper extremity of the femur from the dorsum of the ilium to a position in front of the acetabulum with the aim of lessening deformity and assuring a more secure support in locomotion. This position of over-extension and moderate abduction must be retained for many months by the use of a short spica plaster bandage. In other cases discomfort might be relieved by the application of a pelvic support that would provide a slight degree of lateral pressure and fixation. In children and young patients where the injury involved the articulating extremity of the femur the open operation was indicated. So far as complete fracture was concerned he did not claim that favorable results might not be obtained by any other method if so applied as to accomplish its object, namely, apposition and fixation of the fragments. The speaker said that he had attempted to justify his statement that fracture of the neck of the femur was a neglected subject, and he suggested that this injury would be far less disastrous in its results if the following conclusions were generally accepted: (1) Fracture of the neck of the femur occurs at any age, even in childhood. (2) An injury at the hip, followed by persistent disability, should always suggest fracture, and if one was not expert in the details of physical examination, an *x*-ray picture should be procured if possible. (3) As an impacted fracture must of itself cause disability, one should attempt to reduce it in the manner that had been described, provided sufficient support could be assured. (4) The first essential in the treatment of complete fracture was to appose the fragments. For this purpose, direct traction under anesthesia, followed by fixation in the attitude of abduction, seemed to present certain advantages over the methods ordinarily employed. (5) If union had not followed routine treatment, the open operation was indicated in suitable cases. (6) Support and protection by properly adjusted apparatus was of great advantage during the period of repair, and, in any event, weight bearing should not be permitted until the symptoms indicate that consolidation was complete. (7) The distinction between the two forms of fracture that occurred in young subjects was of importance as influencing treatment. (8) It seemed probable that in the majority of cases treatment might be applied, tentatively at least, with advantage. The standard of success in the treatment of the most favorable cases should be restoration of normal function, and in all one should at least attempt to apply the principles that are recognized as essential to success in the treatment of fractures in other situations.

Dr. De Forest Willard of Philadelphia opened the discussion. He said that among the things that deserved special consideration were the following: (1) The complete and immediate reduction of the deformity under ether; (2) the fact that the patient was somewhat advanced in years, or past the age of 40, did not necessarily mean that the patient would become helpless or hopeless; (3) the after-treatment, especially after they were up and about, should be continued with a view of preventing the deposits of osteophytes about the joints. Even with a fair amount of fixation there was an enormous amount of thickening about these joints which interfered with motion and the subsequent locomotion of the individual. He believed that Dr. Whitman's method of reduction was one of the most efficient measures which could be undertaken. In cases of suspected dislocation or injuries about the joint he made it a rule to always employ anesthesia unless there was some positive contraindication. In every case over 60 years of age he always strived to obtain union. At the Presbyterian Hospital in Philadelphia they met with a great many cases of fracture of the neck of the femur, but he could not say whether they were intra- or extra-capsular, although he believed that nearly all were both. In order that splints might be effective, it was necessary that reduction of the fragments be made; otherwise, although union would occur, it would be with such deformity as would interfere greatly with locomotion. It was absolutely important to have a thorough reduction under ether, and should be done by one who had *x*-ray and clinical knowledge of the points and landmarks about the joint. Every case under 60 or 65 years, he said, should be considered as hopeful when certain methods of treatment were employed. In children one could almost always obtain good union, and one should never despair in their attempts at such. In other words, one should never despair in obtaining good union between the ages of 20 and 60. He referred to a fracture of the femur occurring in a girl as the result of a fall upon the trochanter; the force was so great as to drive in the floor of the acetabulum, yet the shortening was less than an inch, and the patient walked perfectly well but with a slight limp, caused by partial absorption of the bone. With regard to the method of fixation, he did not believe there was anything better, or more comfortable for the patient, or more efficient, than plaster of Paris, especially when applied by one who was expert in it. Many surgeons were not experts in applying this dressing; they did not know how to apply it properly. It received the pain, was very comfortable, and was secure from interference on the part of the patient. The joint should be properly protected and long after; in patients who could not afford splints, plaster of paris should be used, or even a posterior bar would help greatly. The joint should be properly protected to prevent undue motion, and for a long period of time. They needed massage, passive and voluntary motion, but not too excessive until the tendency to osteophytic formation had passed. With regard to the operative treatment of fractures of the neck of the femur, he said there was a certain class of cases in which immediate reduction was advisable—in those cases between the ages of 20 and 50, possibly 60; here hopeful results were obtained. But in the younger cases operation was not required. At these ages one should strive for good functional results. The class of cases most fitted for operation were those which under ether. with traction and abduction employed, showed that the deformity had not been reduced, and that non-union would surely result. In these cases he believed it was proper to operate. The flap operation of opening up the joint and cutting off the shaft of the femur and turning the trochanter did not seem to him a safe initial operation. If one cut the trochanter from the shaft of the femur one got a double fracture, and the operation was a long and tedious one. He believed the simplest operation was to cut down upon the great trochanter and drive a nail or screw in the axis of the neck, through into the head of the bone. The great objection to this procedure was that it left a foreign body which might set up irritation and which might necessitate removal. But that must be expected. If it did not produce caries of the neck of the bone one should be thankful. The immediate operation seemed to him full of hope; he simply drove a nail, a peg or drill through the neck into the hip, being careful not to perforate the cartilage, or going into the joint surface and irritating the acetabulum. If a sinus formed one should immediately cut down and remove the foreign body causing the irritation. The results of operative treatment did not give perfect results. There was stiffening and shortening which followed. It was his experience that when he approached a deep or severe operation about the hip it always was with anxiety, especially when in healthy tissues. He did not have the same anxiety when operating in tuberculous or long-diseased conditions.

Dr. L. A. Stimson asked that the results be judged by the clinical results alone. In the young he saw no reason why Whitman's operation should not lead to restoration of

form and function, but it was of the utmost importance that this method should not be generally adopted in the old. He did not consider a case of fracture of the neck of the femur as helpless unless the line of fracture was through the narrow part of the neck, or where the periosteum was much damaged. With regard to repair in these fractures he said one should bear in mind a point he wished to emphasize, that the neck of the bone was nourished by the same vessels that nourished the head of the bone, and that the neck must share in the reparative process; the granulations must have blood supply; the blood from the head and neck came from the base of the neck; therefore, if a fracture took place through the narrow part of the neck, dividing the periosteum, the head and neck would be cut off from its blood supply, and such cases could not get well. But even in old people repair was possible if the periosteum remain intact. He cautioned against the use of an anesthetic; in cases where one did not know whether he was dealing with a dislocation or fracture, and an anesthetic was given, danger would result from too forcible manipulation of the limb; even destruction of the periosteum of the neck might occur, which would make the case a hopeless one. In hospitals, fractures of the neck of the femur were not desirable; these cases often went from one hospital to another, and finally they would land in the almshouse. Every hospital which transferred such cases would make an entry of "improved," "unimproved," etc., and at last they would die in the almshouse. Statistics regarding these patients were, therefore, very unreliable. Thirty years ago every patient was placed on a stand and traction applied, often with a pulley, the limb then being encased in plaster of Paris. Poor and old people could not stand the rough handling. He thought Dr. Whitman had not said enough regarding the swelling of the soft parts; this to him was a serious matter, for this swelling would mechanically interfere with the treatment, especially in the older people. Fractures of the neck of the femur did not occur like a break of a piece of chalk; the bone was crushed like a handful of snow, and the bone, therefore, could not be brought back to its previous condition. The ordinary treatment of fracture of the neck of the femur was by Buck's extension or vigorous traction, and he believed that the old would recover under such treatment. He did not believe there was any anatomical or clinical evidence that better results could be obtained by wider abduction, although he hoped that results would show him to be in error. One of the first things noticed in these injuries was a thickening of the front of the thigh right over the neck of the bone; after two or three days the fingers around the trochanter could detect this great thickening. This was due to the inflammatory reaction from the traumatism inflicted to the soft parts. In post mortems one found a great overgrowth of bone beyond the intertrochanteric line and at a point where the different muscular fibers had their origin from the bone.

Dr. Virgil P. Gibney said that at the Hospital for Ruptured and Crippled they saw the results of many of these extremely abducted cases, and they were disappointed in them, although he believed that the time had not yet arrived for drawing any definite conclusions regarding this treatment, especially as applied to the older patients. The majority of those who complained were women, with more or less of a neurasthenic temperament. These had been the most difficult cases to treat in the hospital. He agreed with what had been said by Dr. Stimson, and said that years ago surgeons of this city were quite adepts at plaster of Paris work, and especially members of the house staff at Bellevue. People to-day were not such adepts in applying plaster of Paris as they were years ago, but he believed that its proper application in these cases was the *sine qua non* in the treatment.

Dr. George Woolsey said that the limitations in the age of patients to be treated by this method would leave out many of the cases seen at Bellevue Hospital and other general hospitals. In his experience at Bellevue Hospital he said he had not been impressed so much by the advocacy of the various methods of treating the fracture of the neck of the femur as he was in the treatment of the patient himself. It was surprising what good results could be obtained in many cases, so far as function went, when more attention was paid to the building up and nutrition of these patients. The results of the commonly employed treatments in young people had been rather discouraging, and, therefore, he said he had tried the method of Senn, making extension, applying a plaster-of-Paris apparatus, with pressure in the line of the femur, and his results had been excellent so far as function was concerned. He said that lately he had tried extension in the abducted position. In these fractures the only thing that connected the inner with the outer fragment was the periosteum; the periosteum intact was essential for repair, for it was through the periosteum that the blood could reach the head of the bone. The ligamentum teres practically had no office in carrying blood-vessels to the head. Therefore, it should be borne in mind that any strong manipulative force in abduction should be guarded against, and no additional damage to the periosteum be given. He was not much impressed with Dr. Whitman's method in recent cases, but thought it would be of value in those that were ten or eleven weeks old when first seen. Abduction under an anesthetic, with proper extension, he believed would result in good function.

Dr. A. S. Taylor said that, at Dr. Whitman's suggestion, he had performed some experiments on six hips to determine what displacements occurred after division of the bone at different places, and how manipulation should be performed in order to get a proper approximation of the fragments.

The Ethics of Gonorrhea in the Female.—E. S. McKee writes on the difficulties which beset the medical man in the discharge of his duties to his patients, especially female, when gonorrhea is present, and the many complications and difficult questions which appear. A man told him his wife was suffering from the disease, which he had himself given her, and he wished Dr. McKee to treat her. He went, found the diagnosis correct, and conducted the case to recovery. A suit for divorce followed, and the wife tried to make the doctor testify on this point. He refused five times, and was finally arrested and brought before a judge, who, after three appearances and three weeks' time, ordered him to testify. The argument was that the wife was the patient, the husband was not. The wife, the patient, wanted the testimony given, and it was ordered given. In another case, in which the doctor treated the husband and wife both, he was subpœnaed, but could not be made to tell what was the matter with the husband, as he had treated him. Professional secrets the writer considered very important and delicate, and he thought he should not have been ordered to tell what the woman's husband told him in confidence.—*Lancet-Clinic.*

The Use of Bisulphate of Sodium in the Treatment of Typhoid Fever.—John Egerton Cannaday has used the acid sulphate of sodium in the treatment of 85 cases of typhoid fever, as a routine intestinal antiseptic. The bisulphate is used in the strength of seven and one-half grains to the ounce of water, two ounces of this solution being given every three hours. The writer states that it corresponds in acidity to the hydrochloric acid of the stomach and so promotes digestion, which is at a very low ebb in this disease, especially if the temperature runs at all high. The solution is not at all nauseous, and as a rule patients do not object to the taste. The mouths of those patients, in whom treatment was begun early in the course of the disease, kept in excellent condition, with an absence of sordes. Diarrhea and tympanites were uncommon in these cases. The writer has at one time or another tried on different series of cases various intestinal antiseptics, including salol, zinc sulphocarbolate, tincture of iodine, and carbolic acid. He believes that the results have been considerably better when intestinal antiseptics have been used. He concludes that bisulphate of sodium is a non-toxic intestinal antiseptic, that it keeps the mouth clean, promotes digestion by its acidity, prevents tympany, and lessens diarrhea.—*Therapeutic Gazette.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 22, 1905:

	Cases.	Deaths.
Measles	356	16
Diphtheria and Croup	294	42
Scarlet Fever	212	12
Smallpox		
Chickenpox	61	
Tuberculosis	314	189
Typhoid Fever	15	7
Cerebrospinal Meningitis	111	104
Typhus Fever		
Yellow Fever		
Cholera		
Totals	1,363	370

The Principle of Rest in the Treatment of Gastric Ulcer.—Francis D. Boyd believes that the immediate treatment of acute gastric ulcer, with or without hematemesis, resolves itself into the most desirable method of obtaining physiological rest for the stomach, thus permitting healing of the ulcerated surface. Rectal alimentation has the decided disadvantage that there is a very marked increase in intestinal putrefaction while it is practised. Clinically, it is common to find considerable pain and vomiting following the administration of nutrient enemata. The treatment of acute gastric ulcer can be carried out with benefit to the patient in the majority of cases, without the use of rectal alimentation. First, a mild but efficient aperient is given. During the period of physiological rest of the stomach, no food is given by the mouth. Every six hours a pint of warm normal saline solution is syphoned into the bowel by means of a soft catheter and a filter funnel. The craving for water is obviated in this way. In case of any irritability a little morphia may be introduced into the rectum. During the rest period no fluid should be swallowed. The condition of the mouth is of the greatest importance. When it is septic, hematemesis and epigastric hyperesthesia will persist until the condition is improved. An antiseptic mouth wash should be prescribed and the patient should be warned to swallow as little of the buccal secretions as possible. In cases of simple ulcer, treated by rest, all pain and epigastric hyperesthesia should disappear in twenty-four, or, at most, forty-eight hours. If these symptoms persist after three days, the healing process is not going on, and there are probably adhesions. The period of complete rest should extend over from four to six days. Then small quantities of milk should be given. It should be diluted with water, and a little bicarbonate or phosphate of sodium should be added. The lime salts may be precipitated by treatment with citrate of potassium. At the end of the second week the patient can take sufficient milk to maintain nutritive balance. The diet is gradually increased, until at the end of four weeks, an ordinary convalescent diet can be taken without any discomfort. The treatment of gastric hemorrhage, when it is not violent or repeated, is simply the treatment of acute gastric ulcer. The patient with chronic gastric ulcer with stenosis may improve if treated by lavage and careful diet. Lavage, however, will not effect a cure. The relief which surgery affords in these cases seems insufficiently recognized. In cases of chronic gastric ulcer, with no pyloric stenosis, medical treatment may give relief. To get a satisfactory result, the patient must be prepared for at least two months' rest in bed, and for a carefully restricted diet over a much longer period. The circumstances under which the physician should advise surgical interference seem to depend upon the locality of the ulcer. The writer sums up the circumstances under which one would advise surgical interference in chronic gastric ulcer as follows: In chronic gastric ulcer with pyloric stenosis, gastroenterostomy by relieving the pyloric stenosis and resting the ulcer will effect a cure. In chronic gastric ulcer without pyloric stenosis, if the ulcer be situated on the pyloric third of the stomach, gastroenterostomy may effect a cure by giving the ulcer rest. It does not tally with present experience that gastroenterostomy will effect the cure of an ulcer situated outside the pyloric third. The routine performance of gastroenterostomy as has been advocated by some surgeons, irrespective of the situation of the ulcer, is to be deprecated. Such patients improve under the careful dieting and rest of the stomach which follow operation, but relapse of the ulcer may be expected. If the ulcer can be excised, benefit may result. A simple gastroenterostomy will probably result in disappointment.—*The Scottish Medical and Surgical Journal.*

Eclampsia.—Gilman reviews the prominent theories which have been advanced as to the cause of this condition. He makes a plea for the more careful and systematic examination of the urine in pregnant women. He believes that an estimate of the total solids passed in twenty-four hours is fully as valuable as the urea test and may be substituted for it. This total amount may be found by multiplying the number of ounces of urine passed in twenty-four hours by the last two figures of the specific gravity and adding 2 per cent. of the result.—*Boston Medical and Surgical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended April 22, 1905:

SYSTEM AND EXPEDITION IN OFFICE PRACTICE. OFFICE PLANS AND DETAILS.*

BY ROBERT L. DICKINSON, M.D.

NEW YORK.

SURGEON TO BROOKLYN HOSPITAL, CONSULTING GYNECOLOGIST TO ST. MARY'S HOSPITAL, JAMAICA, ASSISTANT OBSTETRICAN TO LONG ISLAND COLLEGE HOSPITAL.

A DOCTOR is handicapped beyond all other men in professional and business careers by being only one-man power. He is able to delegate little. Organization of work by unloading on partners or assistants finds less play than in other livelihoods calling for equal brain power. The more need, therefore, of system and intelligent planning in whatever matters these may expedite and simplify. A man in whose operating room and hospital wards complicated machinery works with smoothness and celerity often fails to engineer the details of his office work with the same executive skill. Yet this is no unimportant matter. The petty annoyances of a long office hour may tell on the nerves more than the same time spent over well organized major operations. It is the sense of hurry, the consciousness of impatience on the part of waiting people, and particularly the chafing at needless delay, that wears on the man in the office. Even for the beginner facilities for quick work will pay. Though he have only a few patients, they have a fashion of bunching at the start or the finish of his office hour, and every one of them begrudges the time lost in the waiting room.

Office Plans.—1. In no way can the doctor save more time than by wise arrangements of his quarters. By an outlay moderate in proportion to its returns, one's efficiency may be doubled. This statement applies less forcibly to the general practitioner than to the surgeon and specialist. Yet even with the physician who abjures throat work, gynecology and minor surgery—if there be any such—annoying delays occur, and there is always the man with a bill to pay, or the crying baby, or a doctor, or the very nervous or very rich patient for whom extra office room will furnish convenience out of all proportion to cost. If the general practitioner does minor surgery or simple gynecology, his office requirements are much the same as those of the surgeon or specialist. Not only in undressing and dressing is time wasted, but in waiting until cocaine takes effect, or bleeding stops, or plaster dries, or pain passes. Not uncommonly, for lack of room, one sends patients home at once who would do better if watched for a short period.

Expedition in office work may be effected in several ways:

1. By well-planned quarters.
2. By completeness of outfit.
3. By appointments, and by selection among waiting patients.
4. In history taking.
5. By proper assistance.

The *general principles that bear on the planning of offices* may be stated as follows:

(a) The offices should be as independent as possible of residential parts of the house. (Figs. 3 and 4.)

(b) The waiting room should be attractive, cheerful and well lighted; with sufficient cubic air space and ventilation, and supplied with comfortable seats, books, pictures, etc.

(c) The different offices should be accessible from the hall without passage through each other (and without necessarily passing through the waiting room), so that entrance or exit is possible for each independently. (Figs. 1 to 8.)

(d) The desk office should be separate from the examining room.

(e) For the busy man two small waiting rooms are better than one large one; two small examining rooms better than one large one. (Fig. 7. Fig. 8.)

(f) The offices should be located in the natural order of progress of the patient, viz., hall, waiting room; desk office; dressing room, with toilet room; examining room; recovery room or dressing room; hall. (Figs. 1, 3, 5, 6, 7, 8.)

(g) Ten feet square is a minimum, but sufficient floor space to accommodate a single office (as distinguished from waiting room or dressing room).

(h) The water closet and the telephone closet should be accessible from both waiting room and offices, preferably by way of the hall. (Figs. 3, 4, 6, 7, 8.)

(i) Walls and doors should be measurably sound-proof.

(j) Doors should be so hung that, when partly open, they screen the occupants of the room, and not primarily for appearance or convenience in entering. (Figs. 2, 5.)

(k) Provision must be made for the elimination of odors of drugs, gas, steam, etc.

(l) Hand washing, after vaginal and rectal examinations, should be possible out of sight of the patient.

(m) Objects likely to trouble or alarm patients should be screened or under cover.

Sound-proof Walls and Doors.—Nowhere are precautions to deaden walls better worth while. In building or altering, the best methods to employ are these: In fire-proof buildings, such as apartment houses or hotels, use fire-proof blocks of terra cotta or asbestos from 2 to 4 inches thick, plastering these with the ordinary hard finish of 7/8-inch plaster. These asbestos and fire-proof blocks are usually set between channel irons in order to stiffen them. Where the story height is not over 9 feet, it is safe to use them without such stiffening.

Where cheaper construction is desired light channel irons may be used, to which are laced two thicknesses of Cabot's deafening felt. On either side of these channel irons is set a wire lath as a backing for plaster. This forms a thin sound-proof partition of great efficiency.

*Read before the Medical Association of the Greater City of New York, June 9, 1902.

Another and still cheaper form of sound-proof partition is made by using the ordinary wooden studs, setting over them on each side a thickness of Cabot's sheathing quilt. Over this quilt is nailed 1x2-inch strips and on this again wooden lath is placed.

Sackett's wall board, a composition of card board and plaster of Paris, to be had in sheets of 32x36 inches, ¼-inch thick, is a very good substitute for lath in sound-proof partitions, and makes, with **⅝-inch of plaster applied to it, a satisfactory deadener of sound.** It saves the extra cost of the quilt

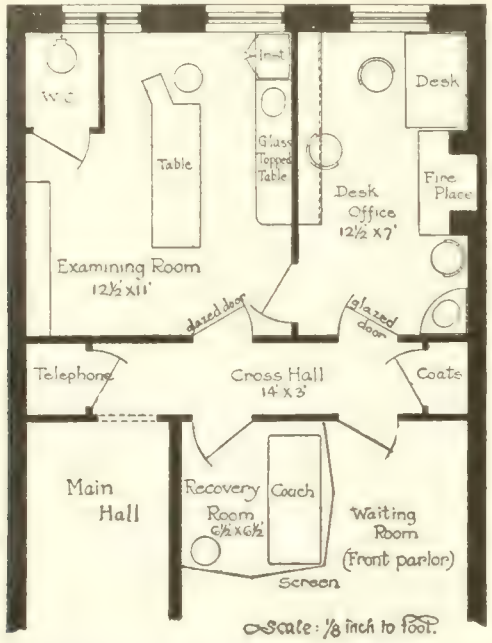

Fig. 1.—Ordinary 20-ft. house without extension altered for offices. Observe the rotation. The door between cross hall and waiting room is opened, and a patient taken into the desk office. When she is sent on to undress in the examining room a second patient may be taken into the desk office. The doctor can get out into his house, or one of the family approach him without going through waiting patients and without disturbing either a patient at the desk, on the table or on the recovery couch—one or all. The toilet is not accessible from the waiting room. The glazed door lights the dark cross hall, but shows figures dimly through, which is undesirable. The plumbing is scattering. There is a sink in the "glass-topped table," and shelves above it. A stool stands at the foot of the examining table the other circles representing chairs. One of these is shown beneath the overhead shelves in the desk office. In a desk office as narrow as this the fireplace would better have been torn out.

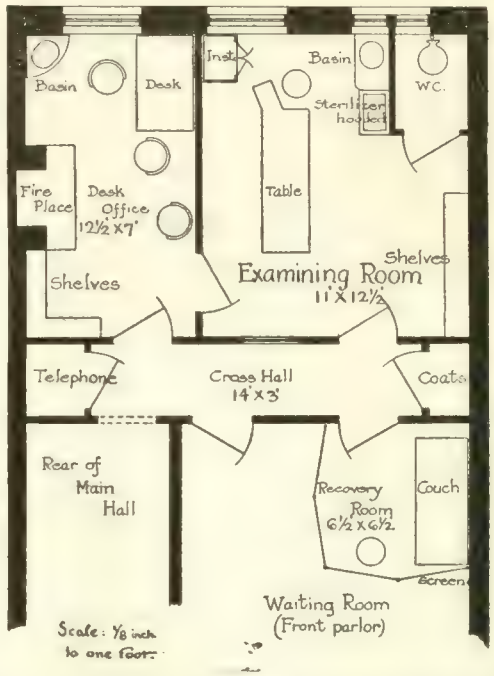

Fig. 2.—20-ft. house, without extension, altered for offices. Alternate plan to Fig. 1. Cross hall better lighted, but toilet still further from main hall; also, doctor, if called to door of his office, can be seen down the main hall. The plumbing is better grouped.

In all the plans the desk office has its own basin, so that after vaginal or other examination, the physician can clean up out of sight of the patient, or can do a minor dressing in either room. In this plan a high window between examining room and cross hall lights the passage, without showing any sign of occupants.

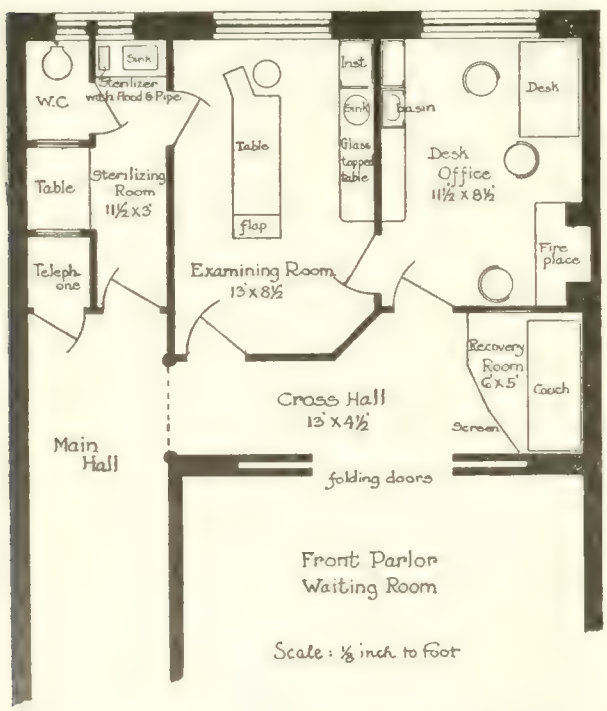

Fig. 6.—Ordinary 25-ft. city house without extension, altered for offices. The cross hall is not well lighted, but has a window near the recovery couch. The cross hall has been widened to give room for couch. The toilet is fairly accessible. Pipes should stand clear of rear wall to avoid freezing.

In all these plans the telephone has been placed in a closet or booth when feasible because a physician's telephone talk should not be overheard. There may be a desk set also. Doors are seen to open awkwardly, apparently, but really in order to screen the patient when the doctor is called to receive a message.

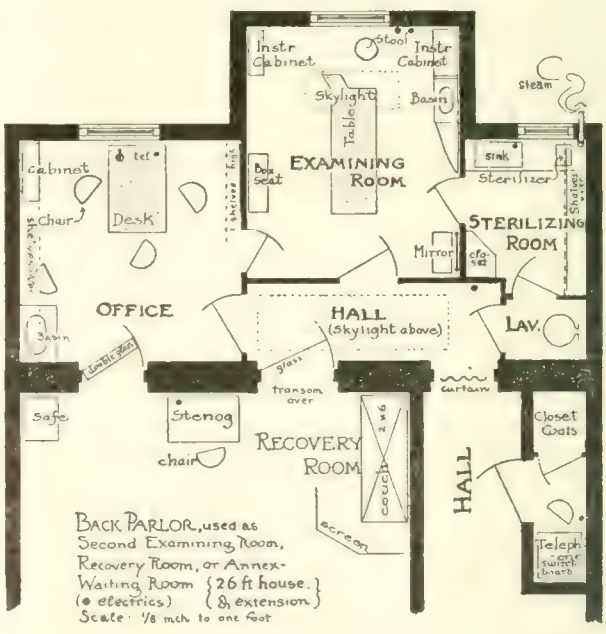

Fig. 7.—Extension on 26-ft. house, being an alteration of an old 11-ft. extension. With this arrangement one patient can be dressing, another undressing, while a third is in the desk office. All rooms and lavatory open into hallway. The success of this office and the many comments on it led to the writing of the article. In bitter weather the plumbing is cut off at night by cocks in the coat closet. All the cuts on the opposing pages are placed for convenience of comparison.

The plan looks crowded, but this is owing largely to the extensive labelling. The watercloset (Lav.) should be enlarged somewhat at the expense of the sterilizing room. The overhead shelving does not trench on floor space, as might appear from the plan. The skylights give fine effects for photography. They have double sash in winter. Such an extension needs its own separate furnace unless neighboring houses project quite as far and a laundry runs beneath. The extension roof should be lower than ceiling of back parlor to allow lighting this dark room through transoms or low windows.

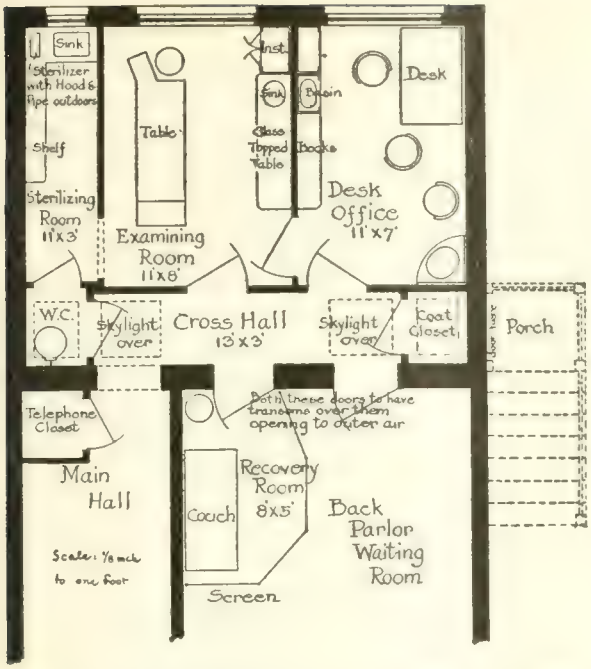

Fig. 3.—Extension on ordinary 20-ft. house. Extension roof is lower than ceiling of waiting room, and transoms light the waiting room. This is a flexible plan, because back parlor can be used as a second examining room if desired, putting waiting patients into the front parlor, either regularly or on occasion. These sizes are all minimum, as 7x11 for desk office is the bigness of a hall bedroom. The plumbing is scattered. The table would stand close to the wall. For a 25 or 30 foot house this arrangement is a good one. For a corner house, or a country house with side entrance, the vestibule will replace the coat closet on this floor.

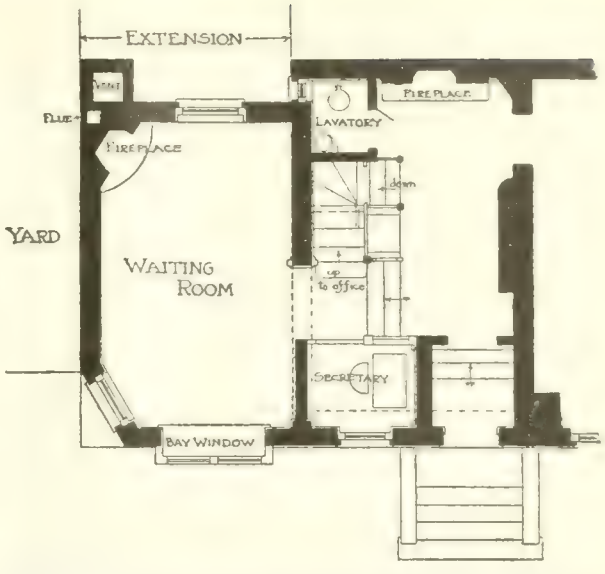

Fig. 4.—Plan of rear end of corner house. Physician's offices are at the rear of second floor of main part of the house. This is a comely plan, with an agreeable waiting room, in the house of a prominent surgeon.

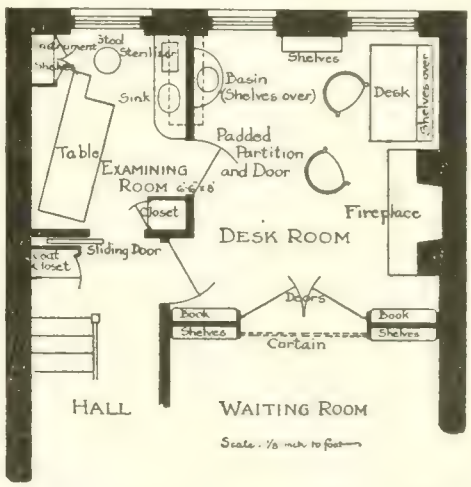

Fig. 5.—A tiny examining room with padded partitions in 18-ft. house, devised by a specialist of small means. It was as compact and handy as the cabin of a ship, and infinitely better than any screen or curtain. There is no toilet nor telephone booth, but entrance to each room from the hall. The examiner's stool at the table might be a boxed-in watercloset seat if the vent could be arranged.

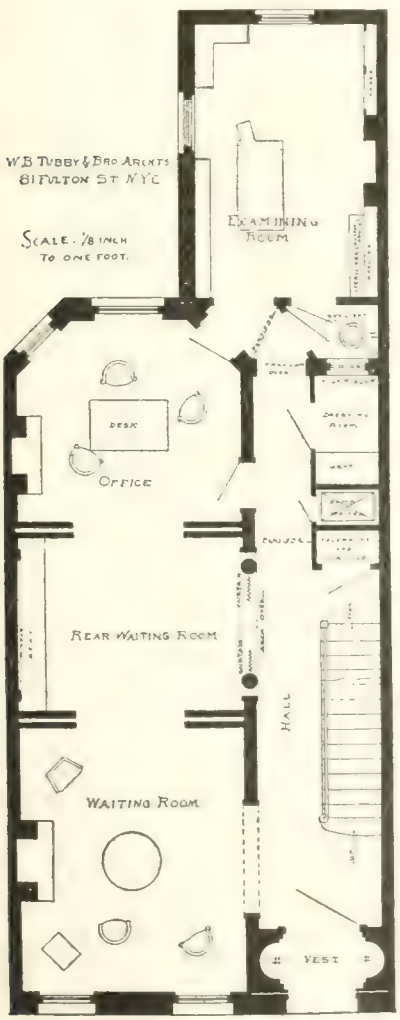

Fig. 8.—Twenty-one-foot city house with narrow extension. Finely proportioned rooms of a leading gynecologist. Double access to desk office and to examining room and to toilet; three rooms can be thrown into one for receptions. Extension, not easy to warm, has fireplace. Desk office should have washstand.

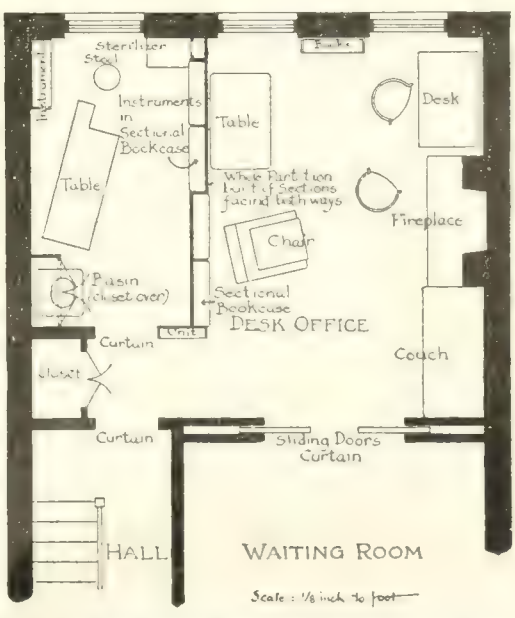

Fig. 9.—The usual 20-foot house with simplest form of division of offices. The partition is built of bookcase units, one-half facing each way. A one-patient office, since one can overhear in the examining room all that goes on in the desk office. A toilet is suggested.

over wooden partitions and is nearly as good in deadening sound. In other words, Sackett's wall board with ⅝-inch of plaster costs about the same as ordinary wood lath with ⅞-inch of plaster.

In two different offices I have seen walls efficiently deadened at small expense by ordinary cheap wadded quilts placed between two thicknesses of wood. The same material tacked on a door and covered with painted burlap is satisfactory. As with all doors, weather strips are necessary. Double sliding doors are more difficult to deal with. A curtain on each side has a good effect. These curtains may be wadded and stiffened if the rooms are small or patients must sit close to the doors. If the upper part of the door opening is arched, a stained glass window can be fitted that will prevent sound passing through this space above the curtain rod.

The doors between waiting room and office should be padded on the inside or hung on one or both sides with relatively heavy curtains, and weather-strips should stop the cracks. Doors may need to be rehung so that a patient on the table or with bared chest may not be in sight when a knock calls the doctor to the door. The screen or curtain enables a patient to dress under cover. It conceals the suggestions of trouble to come, the examining table, the instrument case, and also the disorder left after examination or treatment.

This screen or partition may be of wood, or of wood and leaded glass, or better still, a book shelf of considerable length, but of little thickness. The common error of useless protrusion of shelves is to be avoided. A nine-inch shelf holds even heavy dictionaries, and seven inches is wide enough for most large medical books.

The bookcase units now advertised in every magazine are most useful, whether for books, cards, instruments, dressings or bottles. Some of the newer models do away with the unsightly metal joints. Of these a comely and practical partition may be built, yet it can be altered or shifted at need. (See Fig. 9.)

There are three companies which manufacture special prism glass for throwing light into a room: The Luxfer Prism Company, the New York Prism Company, and Jones & LeBaron. These prisms can be arranged to throw the light at any angle. They are very useful for lighting dark portions of rooms, and well repay their moderate cost.

Glass for covering desks and tables and for shelving, and proper brackets for supporting such shelving with rubber washers, etc., can be obtained of the surgical supply houses or at any of the wholesale plumbers' establishments. The J. L. Mott Company of 88 Beekman street, New York City, keep a full line of these goods.

Flooring.—Carpets are to be condemned, but rugs are allowable in waiting rooms, halls and desk offices. In these hard wood flooring is best. Its first cost is no more than good Brussels carpet, and its life is infinitely longer. Better putty and paint an old board floor than lay carpet. Hard wood costs 9 to 12 cents a square foot. To prevent slipping of rugs in hallways there are sockets let into the floor, with inconspicuous brass pins that go through the rugs at their corners. Matting too, may well be used in the form of rugs. Strips of cocoa matting with rubber binding at the ends, and held by the pins, is very suitable for halls.

For the examining room, the ideal flooring material should probably be listed in this order: Honed glass floor; Mosaic, set in cement; quarry red tile; lignolith; hard wood; linoleum, painted wood.

For the desk office, hard wood is best. For the hallways, mosaic comes first (costing about 70 cents a square foot), then hard wood, costing 9 to 12 cents per square foot.

Plans Grouped.—The ordinary house in city or suburb or country is susceptible of alteration at moderate cost. In these days of electricity, interior rooms have become available by the use of a method of illumination that does not vitiate the air, aided by light wall coloring and bright lighting; by the headlight that is often better than window light, and by the use of the rotary fan. For the sake of clearness we shall try to throw the problems into three groups:

I. The simplest plan consists of two apartments:
   1. Waiting room (parlor or wide hall).
   2. Office (desk office and examining room and sterilizing room in one). (Fig. 9.)

II. An intermediate plan calls for:
   1. Hall.
   2. Waiting room.
   3. Office.
   4. Inner office (including sterilizing and instrument room and laboratory).
   5. Toilet.

III. A complete plan may involve:
   1. Main waiting room.
   2. Small special waiting room.
   3. Desk office.
   4. First examining room.
   5. Second examining room.
   6. Recovery room, or dressing room.
   7. Sterilizing and supply room (laboratory).
   8. Water closet.
   9. Telephone closet. All with independent access to
   10. Private hallway, with separate entrance and vestibule.

I. With the first plan the minimum needs are:

Desk, with light from the left when writing at the desk, and over the doctor's back when he is facing the patient.
Patient's chair, facing the window.
A third seat.
Screen or curtain, to divide office into two parts.
Operating table (or chair) in the best light.
Instrument table.
Wash stand.
Earth closet (if toilet is at a distance).
Medicine shelves.
Book shelves.

In selecting simple quarters of two rooms, it is preferable to pick those with entrance to each room from the hall, and intercommunication between the two rooms.

II. With the second plan a good degree of privacy, speed and convenience are secured. The ordinary house is usually susceptible of this treatment. The rear room or extension of a house 18 or 20 feet wide may be divided by a screen or partition into two offices, and a toilet may also be contrived in the same space. (Figs. 1 to 4.) With a width of 25 feet the problem is simpler, as it is easy to provide for the sterilizing and supply room with its odors and disorders, and the toilet room. A number of examples are given, in the accompanying diagrams, of ordinary town houses of various widths. (Figs. 1 to 8.) Some of these plans represent offices long in successful operation. In all the

designs the deliberate intent has been to give the fullest schemes that the writer and the architects, W. B. Tubby & Brother (of 81 Fulton Street, New York City) could devise, because it is easier for the reader to lop off any particular feature than to plan to place it.

An apartment answers many of the requirements very well, furnishing a number of small rooms, all communicating with the corridor, some of them intercommunicating. A basement on a corner may be thus planned, while the semidetached house, or the country house, presents still easier solutions. In these cases the patients' entrance is best kept separate from the house entrance, even though this makes the matter of attendance on the office door more complicated.

In treating the problem in a house only 18 feet wide, the writer once had a solid partition built and well padded, to be sound-proof. The little room at the rear end of the hall was thus widened to 6½ feet, and was only 8 feet long. A 2-foot door at one end led into the hall, a second door in the side wall led

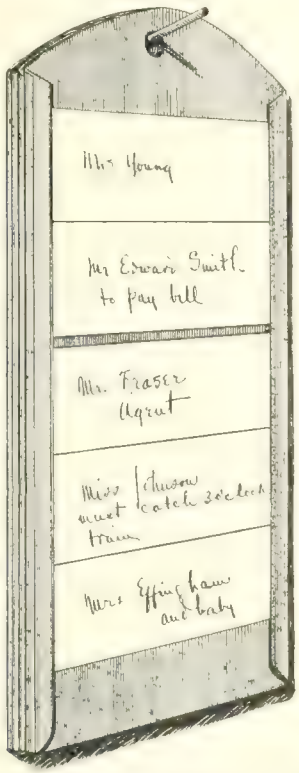

Fig. 10.—Tin slip to hold cards bearing names of patients in the order of their arrival, hung on nail at door of office.

into the desk office, and the window nearly filled the far end. (Fig. 5.) The table stood along the further side wall, a washstand was placed on the near side wall, and above, courses of six-inch shelves with narrow doors, shoulder high. The instrument shelves close to the window on one side and the washstand on the other, faced each other. One of the table drawers held a water closet seat covering a bed pan, to allow a woman to empty her bladder, or furnish a sample of urine. When the doctor sat with his back to the window at the foot of the table, the patient lying on the table and the nurse standing beside it, that room was filled. But the very fact that without moving he could reach all over one end of the room, made the arrangements ridiculously convenient. At any rate, that office has been twice copied in toto by other men. In it one could shout to a deaf lady, without being overheard, those things which may not be said aloud.

III. An example of a relatively complete plan working well under limitations common to cities is shown in Fig. 8. A 26-foot house was altered so that the natural order of progress was possible. Multiple small rooms were preferred to fewer large apartments. Spaciousness in offices was deliberately sacrificed to accessibility. Thus we may find, during an office hour, the following apparently complex, but really orderly proceeding. The surgeon or specialist is sitting at his desk stating his opinion to the family physician. The patient about whom they confer is dressing, after examination in one examining room, helped by the first office nurse. The second office nurse, the attendant of the door and the telephone switchboard in the main hall, is getting ready, on the table in the second examining room, a patient directed to appear for inspection of her pessary or her heating anal fissure. These quick treatments or reports are run off during the necessary waits of long first visits. Perhaps the toilet is being used by a patient from the waiting room, and one of the two telephone trunk lines by another. Or, possibly, the patient who was first seen is faint. She lies down for awhile on the recovery couch, but work in one examining room goes steadily on, the patients not coming in contact with each other. Each nurse has access to the sterilizer. The middle room (Fig. 8) is adaptable, at times being second waiting room, at times second examining room, at times recovery room, at times stenographer's office. Thus there are none of those unproductive waits on the part of man in the office which, in most offices, have to be made good by shortening the verbal interviews or abbreviating the time spent in examination, cocainization, and history-taking.

Waiting Room.—It goes without saying that cheerful outlook and furnishings, books and pictures are desirable. The furniture can be attractive and yet washable if made all of wood, or of wood cane-seated or covered with leather or pantasote. One is less than happy when a lad with unsuspected scarlet fever has wandered about in his waiting room, or if erysipelas handles upholstery—unless one can scrub. A carpet is not liable to infection by contact, but wood floors and rugs are to be preferred. Better than sash curtains in the lower part of the window is a figured or carved screen or lattice of wood, which allows those within to look out, but prevents the passerby from looking in. The Japanese stores contain a selection of these at low cost. No clock should stand in the waiting room. People must forget time. To this end books of short stories pay, and the best are good enough. Magazines grow frowsy. One can do much good teaching by attractive books on hygiene, like Fletcher's "Menticulture," Livingston and Adams' "Grace of Form and Beauty of Vesture," Anne Payson Call's "Power through Repose," Weir Mitchell's "Essays," and the like. Mechanical puzzles are much played with by grown people as well as by children. A wood fire in winter, an electric fan and ice water in summer, a table with writing conveniences for the busy man or woman, a plate of fruit, with finger bowls and napkins—these merely need to be mentioned. He who can afford them will.

To light that portion of the waiting room farthest from the windows, so that one may read by fairly diffused illumination, a device of value is an open grille work or carving in the upper part of the windows. Better still is leaded glass, either clear or of a light or white color. It does not cost much. Beneath this the shade roller is placed, and the curtain is hung from the same level.

A heavy portière at the hall door of the waiting room is a necessary screen, not only to the private

life of the family, but also to those who, while obliged to seek advice from the doctor, do not desire to be observed by the ladies of his family or their guests.

Temptations for thieves, such as clocks, fine vases, or expensive books, are unnecessary. Plaster casts decorate, and books are protected by bookplates or by the name on the inside of the front cover.

A patient leaving the office should not be obliged to pass through rooms where other people are waiting in order to make his exit from the house.

Managers of department stores are learning the value of rest rooms at once comfortable and attractive. The newer railroad stations have well-equipped parlors. The doctor who receives invalids should extend a cordial welcome, remembering how much first impressions count. Short-sighted indeed is that doctor's wife who lets patients wait in cramped hall or dark passage for the sake of the furniture of the empty parlor.

Selection among Patients.—Independent entrances to the offices permit one to call in a doctor, or a man who wants to pay his bill, or a convalescent whose report is brief, while a patient is being made ready or is dressing. It is often desirable to see a feeble or suffering or captious patient out of her turn.

gotten that a shelf nine inches deep will hold big books. Such shelves, flat against the wall, are decorative, and yet out of the way, because they are placed above shoulder height. At the desk, the first requisite is to have histories, accounts, and stationary easily accessible. The main drawer may be partitioned so that the cards are directly under the hand. Vertical files can be bought that will fit any deep drawer, and card catalogue outfits are planned to adjust to any desk space.

The Examining Room.—The best lighted, best ventilated room should be chosen, preferably one facing north. Direct sunlight is desirable neither in summer nor winter. Therefore, the man with morning office hour, if he must choose between east and west, should face west, and the man with the long afternoon hour face east. In building or in reconstructing an extension a skylight should be put in. For photography it is invaluable, also for summer ventilation, and for lighting inner rooms. A light finish on wall and ceiling reflects and diffuses light, and is economical in night illumination. A washable wall, painted or tiled, is best. The light tinted and enamel woodwork should be warm in tint—cream white, for example, not bleak blue white or a cold green. This tinting makes a good reflector of light and a good background for pho-

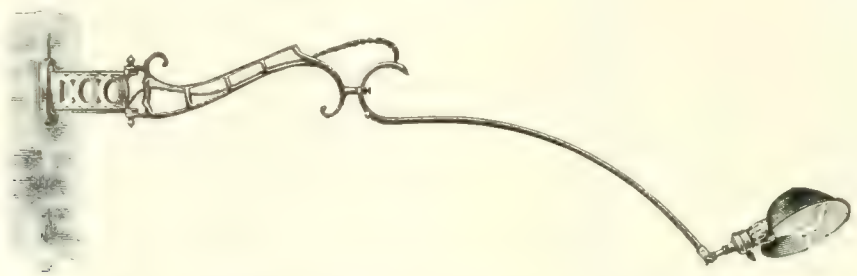

Fig. 11.—Swinging bracket carrying electric light to various heights and angles.

In order to select, a list of arrivals is necessary. A simple and effective plan is as follows: The attendant takes down the names at the door on cheap cards or slips. These, hung in the order of arrival on a simple rack outside the door of the desk office, keep the list in order. This plan also records the business done during an office hour, at the end of which entry may be made on the visiting list. The rack is a simple slip of tin of the width of any cheap standard card, the edges turned over to catch the ends of eight or ten cards. A number of these tin slips hang on a peg. One slip is taken into the office as soon as it is partly filled. (Fig. 10.)

Desk Office.—The few requisites of the history room, to wit, desk, chairs, book shelves, and provision for histories and accounts, make this the least important of the offices. Yet to it is often given space more needed for the equipment required for examinations and treatment. It is rare that there are in the desk office more people than the doctor, the patient, and one or two others, therefore four seats suffice. A washstand placed in the desk office enables one to leave a patient after an examination to clean up out of her sight. This detail is a matter of comment by women.

All this can go into 10x10 or less. A smaller space is not easy to ventilate without draughts. Much room may be saved here by placing the book shelves so that the lowest shelf is five feet from the floor. This will leave all the wall space, except where doors and windows come, available for chairs, desk, and passage room, and at the same time provide generously for books. Three tiers of books may thus be within reach. It should not be for-

tography. The trim should be as flat and free from dust catching panels or beads or mouldings as possible, yet the room need not look bare or lose that architectural beauty which comes from good and sufficient relief. Chairs, stools, table and stands may be enamel white or iron. Glass must cover the tops of stands or tables. The new milk tint glass is good. Glass shelves save much perpendicular space, for the eye can follow the hand back to the rear of a lower shelf, looking through the shelves above, thus allowing close layering of the transparent shelves. Instruments, I hold, should be hidden. It smacks of the charlatan to exhibit rows of gleaming steel horrors. The man who does it should hang in his waiting room the picture of Paré vivisecting the legs of struggling soldiers with red hot soldering irons at his feet, or that of Vesalius posing before a ghastly dissection.

As to the table, individual preferences will always rule. It must be steady, yet on large rollers to move about readily. It must be comfortable to lie on, yet easily cleaned. I prefer enameled wood for its steadiness and simplicity. Patients are somewhat fearful of the iron machines. The best of these is the new Boldt table. Its top adjusts to a variety of inclinations, desirable now that a large proportion of pelvic examinations include the bladder and rectum.

Artificial Light vs. Daylight.—It holds as true for the gynecologist as for the man who deals with the larynx or the ear drum, that artificial light is better than daylight. And for these reasons: Looking into the vagina, we look into a dark cavity, whose surroundings are necessarily pure white. Now, the

more brilliant the light that falls upon the coverings of sheet and towel, the more the pupil contracts and the less it can make of the non-actinic red in the cavity. Let but direct sunlight fall upon the sheet and the cervix disappears. This paradox holds good: The more light, the less one can see. Moreover, when light from a window is used, the patient must adapt herself to the direction of the light. With the head lamp the light follows up and adapts itself to the patient's position, and may sweep about a cavity which is narrowest at its entrance. The same is true of the head mirror, but in a less degree. Both the latter methods differ from window light in directing the greatest intensity of illumination to the spot where it is most needed.

The head mirror is the only quick and simple method of illuminating the female bladder. The head light works perfectly well for the rectum and vagina, is easier to manipulate than the mirror, and does not need handling, as the mirror does. Through a hymen so narrow that the finger tip cannot pass we may painlessly treat a raw cervix, take off a polyp, or dilate a cervix, because we have perfect illumination, tiny specula, and a skill born of the training of the last few years in difficult bladder work.

Electric Head Light.—The band should set firmly without disarranging the hair, and have a light cable long enough to permit the wearer to stand up or move to his washstand without pulling away. One lamp light bears a focussing device. Nothing is better for vaginal work and rectal treatments. The lamp may be connected with a storage battery (generally a troublesome affair) or with any electric light outlet. A Vetter tap goes under any incandescent light, and there is another that permits regulation of the light. This latter is a cylinder 1½ inches by 5 inches in length.

Head Mirror.—For examination of the female bladder or through a tiny opening in the hymen the head mirror is generally used. I have abandoned my complicated and expensive and pain-producing cystoscopes, except in special cases, for the simple tube. The handling of the head mirror is facilitated by substituting a band of flexible metal for the ribbon, so that the hand which twists the swabs need never touch the mirror, one hand putting it on or manipulating it. This support, by means of what might be called a metal hat band, is steadier, but no heavier than the Phillips sagittal suture device. The metal can be rendered sterile, as the ribbon cannot.

To place a light for the head mirror over against the operator, an electric bulb on a handle at the end of a long cord has been used. A far better method employs a light arm swinging from the wall, so jointed that it stays in any desired position. The Faries bracket used by dentists, to be had of the S. S. White Dental Co., is entirely satisfactory and is cheap. There are also brackets for a lamp or a Welsbach or Argand burner, but these are less convenient.

The new electric outfits are exceedingly convenient. From one board connected with the street current galvanic and faradic currents are taken, the head light and cautery can be run, and the electric drill.

Minor Conveniences.—Among the many items that make for comfort and clean work I mention a few that have been tested and found most desirable. The soap jar, which delivers liquid soap, is safer and more convenient than any other method of supplying soap. The Lee jar, in the later egg-shaped pattern, is entirely satisfactory. The tincture of green soap is still the best of the formulas. An infected hand makes no contact with the supply by taking the fluid first on the brush.

In making applications, whether of iodine, carbolic acid, chromic acid, silver nitrate solutions, or whatever is called for in small quantity, I find the dainty little glass receptacle made by McKesson & Robbins for the dentist's peroxide very handy. It is a low, conical glass, with a broad base, holding ten minims. If a dropping tube stands in each bottle and its contents are squirted into the pyrozone cup, and the application is made from this cup, which is boiled afterward, no infection is probable, as it would be when a swab is dipped directly into the bottle of solution. (Fig. 13.) The quarter-grain hypodermic cocaine tablet dropped into this ten minims makes a 5 per cent. solution, just enough for an ordinary local anesthesia.

Duplicate Outfits.—To save time there should be one or more duplicate sets of those instruments which a surgeon or specialist needs constantly. Then

Fig. 13.—Soap jar delivering tincture of green soap into sterile brush.

one set may be in its tray in the sterilizer while another stands in its own tray or rack, ready for use. A sample group would comprise a set of dressing instruments,—for the surgeon, scissors, forceps, probe, pipette; for the gynecologist, a Sims and bivalve speculum, dressing forceps, applicators, sound and instillation tube; or, for the female bladder, No. 7 and No. 8 Kelly cystoscopes and applicators. Such a set stands, after boiling and covering, ready for use.

Sterilizing-Laboratory-Supply Room.—A space not much wider than a corridor—enough for a wide shelf, a chair before it, and for passage behind the chair—will serve for the unkempt room of the plan. Here, in shelves above, supplies are kept. Doors, not hinged on the side, but that slide sidewise or turn upward, protect from dust.

The sterilizer and its steam is best kept out of the offices, even if it has to go into a box of a closet. Wherever it is placed, it should have a hood and a pipe leading outdoors through wall or window to

carry off gas, steam, and heat. The cost is slight, the comfort great.

If the boxing-in is defective a small tube may run upward from the top of the sterilizer into the metal pipe that acts as chimney to carry off the gases, made to fit so snugly as to hold the top out of the way when telescoped by being shoved upward. (See Fig. 14.)

Down to the shelf on which the stove stands the zinc boxing runs on all sides, except in front, where a flap or door is hinged to give access to the stove and boiler within. A two-inch zinc pipe runs up to the cornice, and thence to the outer air through wall or window. A counterpoise or catch holds the flap up. An asparagus kettle meets all ordinary needs for boiling instruments, and may be kept going throughout the office hour. The hood need not be large enough to cover the large sterilizer used for gowns, douche bags, Kelly pad, etc., because such use is only occasional.

Toilet Closet.—A minimum size for a water closet is 2½ x 3 feet. (Fig. 4.) One 3 x 4 feet gives ample space. If it has two doors, one opening from the hall and one from the office (Figs. 3 and 7), they can be locked at one motion by the person

Fig. 13.—Bottle containing fluid for application, with a pipette that acts as cork; glass cup, on watch glass, to receive the needed portion of the solution.

within by means of a long hook reaching from the inside of one door to an eye on the inside of the other. Neither door of the toilet room should be in full view of hall or waiting room, nor should it open only into the examining room or office, otherwise persons who are waiting will not have access to it. (Compare plans 3, 7, 8 with the others.)

One closet may wisely be adapted for a telephone booth. A coat closet may be so used, or a corner of the hall is easily cut off diagonally to close in the telephone. Many of the doctor's messages over the wire are of a nature that renders it desirable for him to be able to shut himself in. The desk set may be on an extension of the same line. Furthermore, this telephone in a hall closet makes it unnecessary for servants to enter the office to answer calls during the doctor's absence.

The Recovery Room.—It is supposed to be unwise for a doctor to have a couch of any form within the closed doors of his office. At any rate, it is unnecessary. Thus all appearance of evil may be avoided. In the rear of the waiting room a screen drawn around a narrow couch or divan gives the necessary privacy and quiet, or the end of a hallway will do. A part or all of what constitutes the secretary's quarters during other parts of the day may be used in this way, as shown on more than one plan. The safe for the ledger is more conveniently placed here also, except that it is well to consider which is likely to be the least hot place in case of a fire. Some men deem their case histories of sufficient value to fit up a safe for them.

Assistants.—By doing special work only on special days, many young men can well afford assistance. In some cases a discreet housemaid acts as office nurse. At the next step the attendant becomes stenographer, accountant, secretary, and nurse in one. For office work a conscientious woman who has learned shorthand can easily be taught surgical cleanliness and the keeping of accounts, because the round of duties is a narrow one, the possibilities of error few, and the supervision constant. The experience and training of the hospital nurse are not necessary as a preparation for ordinary office work,

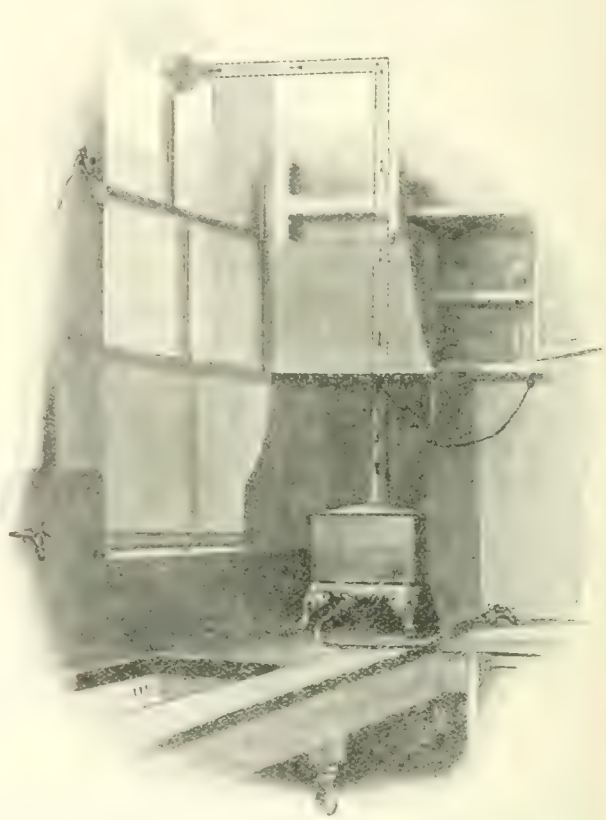

Fig. 14.—Sterilizer under hood. The front of the hood is hinged. From the lid of the sterilizer a tube leads into the pipe.

unless the office nurse is also called upon to assist at outside operations. There is all one nurse can do in a busy one-man office, as of a gynecologist, in the care of offices, instruments, supplies, and dressings; in the preparation of the ever ready operating bags, in keeping the accounts, and typewriting letters and manuscript, to say nothing of attendance at the door and the telephone outside of office hours. She may be trained to the routine of urinalysis. Indeed, it is a matter of no small surprise to the ordinary systematic business man to see the busy doctor himself performing the simple routine duties of laboratory, instrument room or accounts, at a loss of valuable time needed for rest and study or for those things which he alone can do.

Appointments.—As soon as a waiting room gets into the habit of being well filled, and whenever patients persistently complain of the delays, the inauguration of a system of appointments will mark

a long step forward in everybody's comfort. It need not be exclusive. That is, a space may be left unoccupied at the beginning, another at the close, and, if the hours are long, one at the middle part. These arrangements apply to the man whose time in the office covers two or three hours. The patient on leaving the office is simply told by the physician to return in four days, or fourteen, and the door attendant does the rest, entering on a diary the day and hour satisfactory to the patient. In case of inability to keep the appointment, notice is expected, by telephone or mail. Thus the work spreads, even and unhurried, over the time, instead of following the feast-or-famine plan. People do not bunch at the very end of the hour, prolonging it beyond all reason, and in case of an emergency summons or operation the physician can call off his appointments, since his callers are listed.

Printed Directions.—For the surgeon time is saved and exactness insured by a printed list of directions to the nurse for preparation for operation. For all medical men the printed diet lists are essential, as they cover every condition. For children of any age or with almost any disease full diet lists are published. One tears off a page and alters it readily to suit the particular patient.

In addition to the above, every specialist has his own particular set of instructions, which he is forever reiterating. A few simple printed slips economize time, and, while impressing the patient, clinch the instructions, otherwise likely to be ill-remembered. Thus much time is saved, and thus only is accuracy insured.

Rubber Stamps.—An outline of any region or organ on a rubber stamp may now be obtained. Speed and accuracy are served. To make an entry on a diagram takes one-tenth the time that is required to jot down a description and dimensions. A printed outline on the history card of the specialist may serve his purpose better.

Card Ledger and *Card Histories.*—I have written at length on this matter, and shall do so again. Here it will only be in place to urge that the first is of the utmost value, whether to the beginner or to the busy man, and that the second is the only method of record that combines portability, neatness, elasticity, orderliness, and readiness of access.

In closing, let me say that the suggestions here given are not based on theory, but on years of use.

168 Clinton Street, Brooklyn.

THE PRESENT LIMITATIONS OF SERUM THERAPY IN THE TREATMENT OF THE INFECTIOUS DISEASES.*

By HENRY W. BERG, M.D.

NEW YORK,

VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS; ADJUNCT PHYSICIAN TO MOUNT SINAI HOSPITAL; INSTRUCTOR IN INFECTIOUS DISEASES, COLUMBIA UNIVERSITY.

One of the earliest practical results of the studies concerning acquired immunity was the wonderfully successful antitoxin serum therapy in diphtheria. This practical application of the principles upon which acquired immunity depends was in reality premature, evolved by the genius of Behring and his confrères some years before the principles themselves were more than vaguely understood. But while, thanks to the work of Metchnikoff, Ehrlich, and a host of others, the knowledge concerning immunity, antitoxic and bacteriolytic sera has been rapidly developed and amplified, serum therapy has not advanced with anything like equal rapidity.

* Read before the Medical Association of the Greater City of New York, April 10, 1905.

While the logical clinician is now able to understand the *raison d'être* of the success of serum therapy in diphtheria, the broader knowledge of the laws upon which immunity depends has not yet increased the number of infectious diseases which are amenable to curative and prophylactic treatment by antitoxic or antimicrobic sera.

To understand the reason for this it is necessary to recall some essential facts. The pathological bacteria which have been hitherto identified with specific infectious diseases naturally fall into three groups, as far as the production or non-production of toxins is concerned.

First, those bacteria which produce in living cultures outside of the body, best shown in fluid media, as a free secretion, a virulent real toxin. The chief members of this group are the diphtheria and tetanus bacilli. A subsidiary member is *B. pyocyaneus.*

Second, those bacteria which secrete little or no free toxin in living cultures, but do contain a powerful toxin, known as an endotoxin (Buchner-Oppenheim) in the living bacterial cell, which is partly set free only upon the death and disorganization of the bacterial cells. To this class belong by far the largest number of known pathogenic bacteria. Good examples are the pneumococcus, the typhoid bacillus, the streptococci, etc.

Third, those bacteria that produce no free toxins, nor have in the bacterial cells endotoxins of any power, but in which the cell plasma contains other poisons in addition to the protein poisons which all bacterial cells in common contain. For our purpose the most important member of this group is the tubercle bacillus.

The importance of such a classification will be evident when it is recalled that in the diseases with the causation of which the bacteria belonging to the first group have been identified, there is present a local growth of the specific bacteria at some favorite site, together with a more or less general toxemia to which are due the constitutional manifestations of the disease. The toxic products are absorbed by the lymphatics and blood vessels and carried throughout the system. This does not preclude the spread to new centers of bacterial growth either by direct extension or by a limited dissemination of the bacteria themselves by means of the circulation. But the toxin and its dissemination are the important factors. On the other hand, in those numerous diseases in which bacteria belonging to the second group are the pathogenetic factors, there is practically no free toxin produced, to be absorbed and carried through the circulating and lymphatic vessels. The pathological changes in the cells, tissues, and organs are due to the bacteria themselves, and while endotoxins are set free on the destruction of the bacteria, and their absorption does give rise to toxic symptoms, it is evident that its quantity depends upon the quantity of bacterial growth. Furthermore, these endotoxins are not as toxic as the real toxins produced by the bacteria belonging to the first group. In a word, in this group the microbes are the important and direct pathogenic element, as are the free toxins in the first group.

In the third group the symptoms of the disease are due to the bacterial growth, poisons in the cell's plasma and protein contents of the bacteria and the pathological changes which result from their influence. There are no toxins or endotoxins.

It is unnecessary to say here that all three groups of these infections may be complicated by mixed infections in which organisms of various kinds may take part.

Studies of the methods by which an acquired immunity can be induced in the living body which has

become the seat of an infectious disease have shown that the diseases due to the bacteria of the first group can be logically treated by antagonizing the free toxin, by the injection of the blood serum of an animal which has been immunized to that toxin. Such immunization is accomplished by repeated injections of the toxin until the animal no longer reacts to the largest and most virulent possible doses. The serum of such an animal contains antitoxins which enter into chemical combination with the toxins in the blood of the diseased animal and neutralize it. Diseases due to the bacteria of the second group can *not* be treated by such antitoxic sera, because the bacteria belonging to this group do not secrete a free toxin in the course of their growth, or practically do not, or at least no toxin of sufficient virulence for purposes of immunizing animals. Apart from that, in the diseases produced by this group the pathogenetic factors are the bacteria, and antitoxic sera would not antagonize them nor inhibit their growth. For example, even the diphtheria bacillus grows excellently in diphtheria antitoxic serum, as does also the diplococcus of Weixelbaum. So that in these diseases we are logically forced to rely upon antimicrobic sera which produce immunity in an infected animal by producing a bacteriolytic or destructive action upon the bacteria in the tissues and fluids of the body. Such a curative serum is produced by immunizing animals to repeated injections of virulent pure cultures of the bacteria against which it is sought to immunize the animal. The blood serum of such an animal contains an anti-body, comparatively stable, known as the immune body, which is bacteriolytic, however, only in the presence of an unstable body present in the blood serum in the living body and in freshly drawn serum; this is called the alexin, or complement. This alexin, so necessary to the bacteriolytic action of the antimicrobic serum, is present in very small quantity in the blood serum of the living body, hence one of the reasons for the inefficiency of the antimicrobic sera. For the alexin is rapidly destroyed when the blood serum has left the living body, so that the antiserum soon contains none of it, while that present in the body of the patient is insufficient to enable the antimicrobic serum to neutralize more than a limited quantity of the bacteria. Wassermann has advised that the necessary alexin be supplied by injecting with the antisera fresh normal ox or horse serum—surely a difficult thing to accomplish.

As to the diseases dependent upon bacteria belonging to the third group, medicine has as yet received so little encouragement in the treatment of such diseases, as tuberculosis by a therapeutic serum, that so limited a paper as this may well leave this portion of the subject to more minute and special investigation.

In the case of both the antitoxins and antimicrobic sera, the therapeutic action, both curative and prophylactic, is only potential, and not positive in any individual case. It is true that, for instance, in the laboratory experiment a given fixed quantity of diphtheria antitoxin will safely antagonize and neutralize the effect of a fatal dose of diphtheria toxin when both are injected simultaneously into an animal, or when the injection of the antitoxin immediately follows the injection of the toxin. Yet it is apparent that the conditions present in the laboratory experiment are not duplicated in the sick room. First and foremost is the element of time; the injection of the antitoxin does not immediately follow the infection of the patient. Even were the antitoxin injected on the first appearance of pseudo membrane in the throat, the antitoxic injection would still be as many days behind the laboratory experiment as is indicated by the duration of the incubation period of the infection in the given patient. Indeed, when this fact is taken into consideration, it is marvelous that such magnificent results from the antitoxin treatment of diphtheria are obtained. For it is essential that the antitoxin of the injected serum come in contact with the toxin in such a condition that it can enter into chemical combination with it. In other words, it can only bind the toxin which it finds free in the blood and tissues. That which has already entered into firm combination with the body cells, for some of which it has a selective action, is no longer amenable to neutralization by antitoxin. Hence one of the important practical limitations to the efficiency of the antitoxic sera in therapy is the length of time that has elapsed since the infection has occurred. The Ehrlich side chain theory enables us to comprehend why it is that in spite of considerable lapse of time, the antitoxic sera are effective. The toxin molecule becomes anchored to the body cell by a certain atomic group or side chain which Ehrlich terms the haptophore group; but its toxic action upon the cell does not take place until after some time (the incubation period), when it is further attached to the body cell by another atomic group, the toxophore group. The body cell, on the other hand, possesses corresponding side chains to unite with those of the toxin molecule. These side chains are termed the haptophile and toxophile groups. If the antitoxin enters the circulation before the toxin molecule has become attached to the cell by its toxophore group, the toxophile group of the antitoxin molecule chemically binds the toxophore group of the toxin molecule, and thus prevents the union with the toxophile group of the cell. In this case, and that is the usual condition in the curative use of antitoxin sera, a much larger amount of antitoxin is needed than would have been required if the toxin were free in the circulation and no union with the living cell had taken place. Our present clinical and bacteriological knowledge, therefore, enable us to lay down certain limitations to the use of antitoxic sera in the treatment of diseases produced by the toxic bacteria belonging to our first group. These are:

(1) That the bacteriological cause of the disease must be positively identified and known.

(2) That it must be an organism which produces a free specific toxin, and virulent enough to be effective in the immunization of animals.

(3) That the experimental injection of the antitoxic serum in sufficient quantities be successful in saving animals from death when injected with or immediately after a fatal dose of the toxin specific to the organism.

(4) The bacterial cause and its toxin being both specific, the specificity of the action of the antitoxic serum follows as a natural sequence and must be recognized.

(5) The combination between toxin and antitoxin being a chemical one, there must be an absolute quantitative relation between the amount of toxin injected and the quantity of antitoxin required to neutralize it.

(6) That the antitoxin, when used for curative purposes, must be injected before the union of the toxin with animal cells, has become sufficiently firm to cause pathological and destructive changes in the body cells, tissues and organs. For the antitoxin only antagonizes and neutralizes free or partly free toxin. The time element is, therefore, of importance in antitoxic serum therapy. It must be remembered, however, that even where pathological changes have already occurred, the neutralization by antitoxin of

subsequent toxin that may be developed prevents further pathological changes and enables the system to cure those that have already occurred. The process is further aided in diphtheria by the use of local therapy to the site of the bacterial growth for the destruction of it and its pseudo-membranous deposit.

It is on account of this last limitation that tetanus antitoxic serum therapy is so much less efficacious than the antitoxic serum therapy of diphtheria. In the latter disease the local throat lesion, with its clinical symptoms, appears somewhat before or early in the toxemia, so that the antitoxin is enabled to successfully antagonize the free toxin in the blood and tissues. In tetanus, on the other hand, the infection occurs, but gives rise to no clinical symptoms until the toxin has entered into a close combination with the nerve cells of the brain and spinal cord, for which this toxin has a selective affinity. Then only are clinical symptoms manifested, and this is too late for the tetanus antitoxin to have any effect Experimentally it has been shown that a very short time (a few seconds) after tetanus toxin has been injected into the blood of animals it rapidly disappears from the circulation and becomes fixed in the central nervous system. As I have said before, this seems to be the keynote of the non-success of antitoxin serum therapy in the treatment of tetanus.

The first and second of the limitations which we have laid down require no amplification. It goes without saying that the identification of a bacterium is necessary before its toxin can be isolated or known, and such bacterium and its toxin must be identified as the specific bacteriological cause of a disease, before immunity can be established in an animal and a specific antitoxic serum be produced. Infectious diseases whose bacteriological cause is not known can not be treated by antitoxic sera. The use of diphtheria antitoxin, *e.g.* for the cure of infectious diseases of undetermined bacteriological pathogenesis would be futile and illogical, however much empirically supported by misleading statistics. It follows, too, that the effective preparation of antitoxic sera from immunization of animals with culture products obtained from non-toxin producing bacteria is impossible, as, for instance, the failure to produce a streptococcus antitoxic serum, although antistreptococcus serum is a logical and therapeutically somewhat effective product in certain diseases.

The logic of the third limitation follows from the nature of the chemical antagonism between toxin and antitoxin. Surely if the life saving effect does not occur under conditions present in the laboratory experiment on animals, it cannot occur under the conditions present in disease.

The fourth limitation, that the action of the antitoxic sera is absolutely specific, follows from the biological data which enter into its production. He is an enemy to the future progress of serum therapy who advocates the therapeutic utility of the antitoxic serum specific to one organism for the cure of the toxic or microbic ravages of another. There is no logic in such a recommendation. Rather is it the worst kind of empiricism. Preferable by far to adhere to the symptomatic treatment of disease than rend asunder the complete logical chain upon which legitimate serum therapy depends. Such therapeutic experiments as the use of diphtheria antitoxin in the treatment of pneumonia, or diphtheria antitoxin in the treatment of cerebrospinal meningitis epidemica have no bacteriological groundwork upon which to rest, and are repugnant to the principles of scientific serum therapy. Both pneumonia and cerebrospinal meningitis vary from time to time in severity and in their death rate. The results in a number of cases, even if large, treated on such illogical and inconclusive serum therapeutic basis, teach nothing as to the efficiency of such therapy. Such methods fall into disuse long before they have gained even a limited vogue. It is true that the injection in limited quantity of a heterologous serum, like horse serum, whether it is from an immunized or non-immunized animal, has a tendency, as Metchnikoff has shown, to stimulate phagocytosis, and may thus aid secondarily in the disintegration of any pathogenic organism that happens to be floating in the blood. But this would be as readily accomplished by the injection of non-immunized horse serum. Even this is not probable, for reasons which we have no opportunity of discussing here.

The fifth limitation as to the absolute quantitative relation between toxin and antitoxin would give us exact indications for the dosage of antitoxic sera did we but know how much toxin has been produced and remains in the body of the patient. This we have at present no clinical means of estimating. The therapeutic indication is, therefore, to inject sufficient antitoxin to produce the desired result, provided no symptoms contraindicating further injections occur. The element of the duration of time that the patient has been suffering from the disease becomes an important factor. For it is found in diphtheria that the longer the patient or animal has been suffering from the disease the larger the quantity of antitoxin required to produce a beneficial effect. And it appears that an arithmetical progress in the time since the infection requires a geometrical progressive increase in dose of antitoxin necessary to antagonize the toxin that causes the disease. This is partly due to the increased amount of toxin in the body, but far more to the fact that toxin molecules that have entered into *partial* combination with the body cells require a large excess of antitoxin to drag them away from their union with the living cell.

Thus also clinical and bacteriological data derived from studies in immunity from infections due to organisms belonging to our second group permit the formulating of certain essential prerequisites to the use of antimicrobic or bacteriolytic sera in the treatment of such infectious diseases. These are:

(1) The bacteriological cause of the disease must be positively identified and known.

(2) The experimental injection of the bacteriolytic serum in sufficient doses must be successful in saving animals from death when injected with or immediately after a lethal dose of a living corresponding bacterial culture.

(3) The bacterial cause of the disease being specific, the specificity of the bacteriolytic serum follows as a natural sequence.

(4) Since the antiserum has a destructive or bacteriolytic action upon the pathogenetic bacteria, their action being dependent upon the combined presence of two known substances, namely, the alexin or complement (an unstable substance present in the normal living body and in fresh serum) and the immune body (present in bacteriolytic sera), and since only a small amount of the alexin is present in the body, in quantity sufficient to produce only a very limited bacteriolysis, it follows that, unless the antibacterial serum be freshly drawn, thus securing the unchanged alexin present in the blood of the immune animal, the antimicrobic action of the bacteriolytic sera is limited by the insufficient amount of alexin present in the body of the patient. Wassermann, recognizing the impossibility of having the bacteriolytic sera freshly obtained for each case, advises for this purpose the injection of the fresh serum of non-immunized horses or oxen in addition to the antiserum itself. This recommendation, however, can

hardly, for obvious reasons, be considered as having solved the problem.

Under all circumstances it is absolutely necessary that the bacteriolytic serum be fresh.

(5) The bacteriolytic sera have a quantitative relation to the amount of bacteria which they can destroy. At best the antisera protect only against a limited amount of bacterial infection. When this increases beyond a certain figure no amount of antiserum will protect or cure the animal. Hence very large doses are necessary, sometimes repeated. Thus the antistreptococcus serum is used in doses of 150 to 250 c.c., repeated if symptoms do not improve.

(6) While enthusiasts might claim that the bacteriolytic action of the antisera seen in animals which are the subject of experimental infections occur also in patients suffering from infectious diseases, no curative effect can possibly occur with regard to pathological changes which have already been produced by the bacterial infection. So that the later the antiserum is used the less the chance of its having any curative effect.

Bacteriolytic sera have been prepared for the serum therapy of a number of the infectious diseases, but such sera have hitherto had little or no efficacy. Thus an antistreptococcus serum has been prepared for use in cases of septic infection by streptococcus [illegible]s or erysipelatis. Pane has prepared an antipneumococcic serum, Calmette an antiplague serum, and antisera have been prepared for the treatment of typhoid fever, cholera, tuberculosis, anthrax, yellow fever, suppurations due to pyogenes aureus, and infections with the colon bacillus and the bacillus dysenteriæ. Attempts have been made to produce antisera in almost every infectious dis[illegible] the bacterial cause of which is known. It is [illegible] to generalize and say that none of these sera have been therapeutically effective, an occasional report of one or more apparently hopeless cases brilliantly cured to the contrary notwithstanding. These failures are probably due to one or more of the limitations inherent in all bacteriolytic sera, especially to the impossibility of providing sufficient alexin [illegible]ent, and the difficulty of recognizing most of the infectious diseases until symptoms depending upon gross pathological changes have occurred. The serum therapy is thus applied too late. Finally, even the largest practicable doses of the bacteriolytic sera can destroy only a limited amount of bacteria, entirely insufficient to free the patient from the bacterial infection.

Such automicrobic sera have, however, been prepared for use even in diseases the bacterial causes of which have not yet been identified or positively recognized, as, for instance, the antiserum prepared for the treatment of syphilis, which may be dismissed from serious consideration. Time enough to speak of such a serum when the bacteriological cause of syphilis is known.

In scarlet fever, too, notwithstanding that the bacterial cause is not yet generally recognized, an antiserum has been prepared which may not thus summarily be dismissed from consideration, owing to the fact that eminent clinicians have ascribed to it remarkable efficacy in the treatment of this disease. Marmorek and Aronson both used an antistreptococcus serum in the treatment of scarlatina. The former used an erysipelas streptococcus, the virulence of which had been increased by repeated passage through animals. With this virulent culture of streptococcus horses were immunized and the serum of such immune horses used for the treatment of scarlet fever, with the object of preventing the complications due to mixed infections with the streptococcus, and thus diminishing the death rate. Aronson's serum was prepared in a similar way, except that the original culture was from a streptococcus obtained from the bone marrow of a patient dead from scarlet fever. He also increased the virulence of the organism by repeated passage through animals. Tavel, and, later, Moser, prepared an antistreptococcus serum in which the streptococcus was taken from the blood of patients dying of virulent scarlatina. They did not attempt to increase the virulence of the organism by repeated passage through animals, claiming that such frequent passage through animals altered the biological character of the streptococcus, so that it was no longer identical with the species of streptococcus which complicated the scarlet fever. Neither Tavel nor Moser claims that the streptococcus is the bacteriological cause of scarlet fever; nevertheless Moser ascribes to the antistreptococcus serum which he has thus prepared brilliant curative virtues in the treatment of scarlet fever. In the St. Anna Kinderspital in Vienna there were cases of this disease:

			Died.	Per cent.
[illegible]	[illegible]	174	[illegible] which 22	12.89
Treated without	[illegible]	268	" 44	16.41
serum in	1900	205	" 33	12.45
Treated with	[illegible]	389	" 35	8.99
[illegible] Moser	[illegible]	478	" 32	6.70

Escherich reports (*Wiener klinische Wochenschrift*, No. 23, 1903) 112 cases of varying severity treated by serum with 17 deaths, equal to 15.17 per cent.

Pospischill (*Wiener klinische Wochenschrift*, No. 15, 1903) reports 26 severe cases treated, of which 12 died, almost 50 per cent. Moser himself reports 48 cases of varying severity treated by serum with 13 deaths, over 25 per cent. (*Wiener klinische Wochenschrift*, No. 44, 1903).

I may be permitted to compare these statistics with those of the Riverside Hospital, of which I am an attending physician. At that institution we treated during the year 1904 899 cases of scarlatina of every grade of severity, with 75 deaths; 17 of these deaths occurred within twenty-four hours of admission, the cases being admitted in practically hopeless condition. They should properly be excluded, leaving us a death rate of 6.45 per cent., or, if included, a death rate of 8.34 per cent.

From the statistics I have quoted it will be seen that our death rate, on classical lines of treatment and in a very large number of cases, is lower than the results from the Moser treatment in the St. Anna Kinderspital for 1901. And, excluding our 17 practically moribund cases, the 6.45 per cent. death rate is better than the best reported results from the Moser treatment in the St. Anna Kinderspital, those for 1902. It must not be forgotten that the Riverside service cannot select its cases, but must take all that are offered, the hospital being in charge of the Health Department.

Notwithstanding, however, that the statistics are not convincing nor impressive in favor of the Moser treatment, we should not be disposed to condemn this method of treating scarlet fever were there other good reasons in favor of its adoption. But there are unfortunately none such.

This serum violates the first logical essential for the production of an antiserum. The bacterial cause of scarlet fever is unknown, and while many of the complications are due to mixed infections with the pus organisms, surely the death rate in scarlet fever is not due wholly to the mixed infections. It is begging the question to inject a serum for the prevention of complications and leave the primary disease untreated. Indeed, Moser, in his later reports, claims far more for his serum. He records a few tempera-

ture charts in which he shows that the fever curve in these few cases, twenty-four hours after the injection, underwent a critical drop, by which he implies, although he does not so state, that his serum antagonizes or neutralizes the toxic or bacterial cause of the fever in scarlet fever; in other words, antagonizes the bacterial cause of the disease. In a few cases treated in the Reception Pavilion of the Willard Parker Hospital in 1902 I did not observe any such effect produced on the temperature curve by the injection of the serum. While it is the rule for the fever in scarlet fever to be maintained at the maximum temperature for the given case until the eruption has covered the body, and then gradually to resolve by lysis, it is not at all rare to observe in a case that begins with a high temperature a critical drop before the third day, when the eruption has scarcely covered the body. In these cases it will generally be found that the abnormally high temperature was due to the severity of the throat manifestations, and that the subsidence of these results in a critical drop of the temperature.

Furthermore, what has been said concerning the necessity of adding the unstable alexin to enable the immune body to be effective in bacteriocidal serum therapy must not be forgotten. If the labors of Buchner, Ehrlich, Morgenroth, and Metchnikoff are of any value, the Moser or other similar sera must be absolutely worthless unless such antisera are accompanied by injections of fresh non-immunized horse serum to supply the alexin or complement. Again, while Moser uses large doses of his serum, 150 to 250 c.c., owing to the proven fact that the antisera only antagonize a limited amount of bacteria, yet in severe cases the bacterial mass must be so great that no amount of the bactericidal serum will antagonize it. It is true also that small quantities of a heterologous serum exert a phagocytic activity, yet large quantities of a heterologous serum, like horse serum, exert henolytic properties. I believe that the body of even our youngest patient is able to dispose of 200 c.c. of a heterologous serum; nevertheless it does seem reasonable to believe that in such large doses of a foreign serum injected into our young patients, there is much that is objectionable. These and many other considerations prove the unscientific basis upon which the antistreptococcus serum therapy of scarlet fever rests.

These are some of the limitations of serum therapy at the present time. Many of them will be removed by future advances in bacteriological and biological knowledge. Let us not as clinicians hamper the master minds devoted to the solution of the intricate problems involved, and discredit the scientific structure which they are carefully erecting, fact on fact, by the empirical and premature use of such antisera in the treatment of disease for which there is no known scientific basis, but which, on the contrary militate against the fundamental principles of immunity.

923 Madison Avenue

THE PRESENT STATUS OF RONTGEN RAY THERAPY.*

By RUSSELL H. BOGGS, M.D.,

PITTSBURG, PA.

A wide divergence of opinion exists among physicians in regard to the uses of the *x*-ray as a therapeutic agent. Notwithstanding the vast amount of work that has been done in the past four years with Röntgen rays, it is really astounding how little physicians know what can be actually accomplished by their use. That results have not been more positive and the claims for the *x*-ray set forth with a greater degree of positiveness as regards its effect as a therapeutic agent for certain diseases, is no doubt due largely to the fact that every physician has more or less confined himself to his own work, and has not digested thoroughly all that has been done in the same field by others. The time has come, however, when every one practising medicine must realize the value of the *x*-ray, both as a diagnostic and as a therapeutic agent. Radiotherapy has a broad field of usefulness, and it is essential to the best interests of the patient that a certain few diseases be treated by its means.

The *x*-ray has been abused by a few physicians in applying it, by a certain few who have overestimated its value, and by a large number of skeptics, who could not see how the *x*-ray could produce any results whatever in diseased tissues. If the opinion of skeptics were accepted, no advancement in medicine would have ever taken place. How many scoffed at the idea of vaccination, and how slow were many in adopting antitoxin as a therapeutic agent! The *x*-ray at the present time is going through a similar test, and even now, with exact and proper technic, it has attained a place in medicine as important as either of the agents mentioned.

Either success or failure in many cases of carcinoma, as well as other diseases, must be attributed to technic. Even at the present time no one's technic is perfect; but there is a standard by which effective work can be accomplished. With the best apparatus and meters to register the current from the time it passes through the primary induction coil until it goes into the tube, it is possible to account for a few of the failures which have occurred in the past; but still the experience of the operator is a better guide than all the meters to determine the penetration and the amount of chemical rays which are being given off from a tube. On applying the rays it is absolutely necessary to know what quantity and quality of rays are absorbed, and this can be accomplished only by an operator of judgment and experience. Among experienced operators and those who are attaining results, it is a well-known fact that scarcely any two diseases require the same therapeutic dose. If the operator can judge the quality of the rays, as well as the quantity absorbed, then he can administer the same therapeutic doses, and be sure of obtaining similar results in each condition. Too much work is done in a careless manner. I know a few surgeons who are having every case of carcinoma treated after operation, and as I have had the privilege of examining many of these cases, I have only seen a few in which a therapeutic dose was given. By this I mean that, after twenty treatments were given, no tanning or effect of the rays could be seen. I want to emphasize the necessity of giving a therapeutic dose. In deciding upon this, too much dependence must not be put upon the Röntgen ray ammeter. While this is a valuable instrument, it will not do everything claimed for it by the manufacturers. At a certain high vacuum a tube will practically give off very few chemical rays, and if a patient were exposed a long time to such a light, very little, if any, action on the diseased tissues, could, except a slight stimulation, be produced, while if the tube should pass a volume of current, a large number of rays would be given off and a curative effect would result. It is just as reasonable to expect to force a large amount of water through a pipe one-eighth of an inch in diameter, and do this in a time which, by mathematical calculations, would be impossible, as it is to attempt to force a volume

*Read before the Detroit Academy of Medicine, January 10, 1905.

of current through a tube so high that the internal resistance is so great that the amount of current which passes can scarcely be measured by the Röntgen ray ammeter, and at the same time expect the tube to give off a large quantity of chemical rays. This is what many are attempting.

A great deal has been written in regard to the detrimental effect of the *x*-ray upon the operator. That the *x*-ray will affect the operator, unless he uses the necessary caution, is a well-known fact, and if he did not do this it would be useless to apply the rays to diseased tissues. Any effect which has been produced upon the operator in the past two years shows that he has not familiarized himself with what is going on in the *x*-ray world, or else he has been exceedingly careless, and carelessness is not permissible in any branch of medicine. If a physician were careless he might cut his fingers, but the surgeon would not condemn the knife he used. In regard to Edison's assistant and a few others who were injured by the *x*-ray, it is only necessary to state that they did not understand the action on tissues of the energy with which they were working. A few years ago it was nothing unusual for the operator to sit before the fluoroscope for a considerable length of time studying the light, its effect on tissues being comparatively little known at that time. It was then claimed that the tanning produced by the rays protected the patient from further injurious effects, in the same way that sunburn protects the skin from further irritation. It is scarcely necessary to state that every one knows this to be untrue. Two years ago, at the time of the meeting of the American Röntgen Ray Society in Chicago, I was considerably burned, and when I saw the effects of the *x*-ray on various operators I realized the necessity of every operator abandoning the fluoroscope, because standing continually before the tube will produce harmful effects upon the operator's body. A fluoroscopic examination usually consumes considerable time, is really practically useless except for the purpose of testing tubes and making minor examinations, and since it is dangerous to the operator, this method should be discarded. Besides, a fluoroscopic examination is not a positive means of diagnosis, and if one takes into consideration the mistakes which have been made by using the fluoroscope instead of making a radiograph, it will readily be seen that results obtained by such methods are practically useless.

Many physicians using the *x*-ray have stated that since they did such a small amount of work (not making more than one or two fluoroscopic examinations a week), it would not affect them in the least. Most fluoroscopic examinations will consume at least ten minutes, and if the operator exposes himself, for this length of time, to an active tube twice a week, he receives what should be a sufficient quantity of *x*-rays to cure a case of lupus, and still these operators think that they can take such dosage every week without its having any injurious effect. This shows that physicians who make such rash statements know very little about the energy they are employing. I cannot impress it too strongly upon every physician to discontinue the use of the fluoroscope for diagnostic purposes, first, on account of the injurious effects produced by its continued use; second, on account of the number of mistakes which have been made. In regard to whether the *x*-ray has any injurious effects on the patient's health when being treated, I have made inquiries from almost all the physicians applying the rays to any extent, and the following, by a very prominent physician of broad experience, covers very well all the answers: "I have not found that the *x*-ray has had the slightest injurious effect on the general health of any patient, although some patients have been treated for from four to six months at intervals." A few physicians have remarked that at least one-half of the patients treated by the rays gain in weight during the first six weeks of treatment. I have noticed this frequently. Therefore, in the hands of a competent operator, the *x*-ray is just as safe a therapeutic agent as morphine or strychnine.

The *x*-ray as a diagnostic and curative agent must be used in a scientific manner if results are to be expected. It is absolutely necessary that the laws which govern light must be taken into consideration, and if the tissues are to be deeply affected, the law must be observed that the intensity of the *x*-ray, like that of light, decreases inversely as the square of the distance. Then, if tissues below the surface of the skin are to be affected, it is necessary to use a different technic from that which is employed for the treatment of skin diseases. In the treatment of the deeper tissues we should not produce a light which will burn the skin three or four times as much as the diseased structures situated two or three inches below the surface. It is necessary in the treatment of such conditions to use a light and such technic that the tissues will be affected nearly uniformly, otherwise very little effect will be produced. On the other hand, in treating a skin disease it is not necessary to burn the tissues two inches below the surface, unless these also are involved. The method of application accounts for many of the failures and successful treatment with the *x*-ray.

Carcinoma.—Sufficient evidence has been produced to gice radiotherapy a very prominent place in the treatment of carcinoma. That the rays should be adopted as the only treatment for carcinoma is a great mistake, and I can positively state that no conservative therapeutist would condemn surgery, any more than a conservative surgeon would condemn the Röntgen rays as a therapeutic agent. All cases of carcinoma, whenever operable, should be referred to the surgeon, and have the mass, or as much of it as possible, removed, and then a series of *x*-ray treatments given. I believe I can safely state that sufficient evidence has accumulated up to the present time to say that if the best interest of the patient is considered, such treatment should be adopted. It is a well known fact that beyond certain points surgical interference in the treatment of carcinoma is useless, and that recurrence in a particular situation after one or two operations leaves the patient without further hope, unless from the Röntgen rays; but even then the rays have done a great deal when the proper technic has been used. Still, the agent must not be overestimated in this class of cases. Now, if the *x*-ray will reduce the size of the tumor, cause the cessation of pain, the disappearance of offensive odors, and arrest the invading progress, why should it not be combined with surgery and the cases rayed before they have become hopeless? Many patients when they come to their physician are hopeless, and the surgeon hesitates or states that the case is very likely to have a recurrence, and that an operation might prolong the patient's life. Now, in these cases, if the combination of surgery and Röntgen ray can cure even a small percentage, it certainly is worth adopting as a routine treatment. At present a number of such cases so treated apparently have been cured. The severity of carcinoma of the breast is shown in Kuttsner's report of 41 operations during twelve years. In each of these 41 cases the supraclavicular glands were enlarged, and not a single case was cured. In this class of cases I am almost positive that, with the combination of Röntgen ray with sur-

gery, at least from 10 to 25 per cent. of these hopeless cases would have been apparently cured and the lives of the remainder prolonged. Up to the present time there has not been much success in the treatment of deep carcinoma. By this I mean carcinoma of the stomach, rectum, or uterus, although the inhibitory action and relief from pain has been marked and reported by a large number of operators. The Röntgen ray occupies an important place in the treatment of epithelioma, as it is effective and leaves very little scar. Still, the cases must be selected, and the general opinion at the present time is that some of the patients should be referred to the surgeon and some treated by the *x*-ray. A safe method, unless the physician has had considerable experience with the treatment of epithelioma, would be to consult a surgeon before the treatment is decided upon.

Tuberculosis.—Sufficient evidence has been given in a number of cases reported by conservative physicans (Murphy, Rodman, Burdick, Pfahler, and others) to give the *x*-rays a place in the treatment of all forms of tuberculosis. However, in making this statement, I wish to warn the physician not to be carried away by the fact that the rays have apparently cured a large percentage of favorable cases, and that it is not advisable to discard any of the older methods, but only to employ the rays as an auxiliary in the treatment. Of tubercular cases, glands and fistulæ are most benefited, and bone lesions the least. Even pulmonary tuberculosis is more susceptible to treatment than when the disease is situated in bone. In the cases of pulmonary tuberculosis in which tubercle bacilli are found, a large percentage of apparent cures have been effected in the early stages, but when the sputum contains not only the bacilli, but also streptococci, the rays, as a rule, have given very poor results. Burdick reports a few instances of this mixed type in which he has had favorable results by the use of the antistreptococcic serum and the Röntgen rays.

Skin Diseases.—It has been six years since skin diseases were first treated by the *x*-ray, and while a large number are benefited by the application of the rays, it is certainly advisable to treat only the most obstinate diseases in this manner, as trivial affections can be relieved by other measures, with less expense to the patient. However, in the treatment of many diseases such as acne, eczema, psoriasis, keloid, nevus, lupus vulgaris and erythematosus, mycosic fungoides, sycosis, and a few others, the Röntgen ray should certainly stand first as a therapeutic agent. A number of cases reported by various men, among them being Allen, Montgomery, Hyde, Fraund, Schiff and Pusey, verify the above statement.

Probably one of the reasons why the *x*-ray is effective when other stimulating agents have failed is that the rays penetrate and reach the affected area. Ordinarily in the treatment of cutaneous disorders the remedies have only a very superficial action.

Conclusions.—(1) that the wide difference of opinion as to the value of the rays is largely due to the manner in which they are applied.

(2) That if the best interests of our patients are to be considered, the rays must be given a place as a therapeutic agent.

(3) That injury to the operators from the rays during the past two years has been due to thoughtlessness or lack of familiarity with what is going on in the *x*-ray world.

(4) That in applying the rays it is essential to know the quality as well as the quantity of the rays absorbed, and that this must be varied to suit each individual case.

(5) That unless the operator has had a wide experience in the treatment of carcinoma, he should always consult a surgeon in each case, as it is certainly by the combination of surgery and *x*-ray that the best results are to be obtained.

RECTAL ABSCESS CONTAINING GONOCOCCI WITHOUT ANY ACCOMPANYING GONORRHEA.

By F. R. STURGIS, M.D.,
NEW YORK.
FORMER CLINICAL PROFESSOR OF VENEREAL DISEASES IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK, ETC.

THE following very interesting case I saw in consultation with Dr. Arthur L. Root of this city, on January 16, 1895, and to his courtesy I am indebted for being able to report the case. The patient was suffering from an abscess about the portour of the anus, right side, which Dr. Root opened in November, 1894, and which was secreting an abundance of apparently laudable pus. No fistulous track could be detected, nor did there seem to be any opening into the bowel. It was simply a medium sized periproctitic abscess which had been discharging for about two months before I saw him. At that time it struck me as being very possibly a case of tuberculous abscess about the anus. On inquiring into his history I obtained the following facts: In February, 1887, he had his first attack of gonorrhea, which lasted for two weeks, and which he treated himself by the use of some patent injection. In July of the following year, 1888, he had a second attack of gonorrhea, followed by an epididymitis of the right side, which, according to the usual custom, checked the discharge, and when the testicle recovered the discharge did not return. Soon after, a small abscess formed in his epididymis, which was treated by Dr. Root and which finally got well.

In 1891 another epididymal abscess occurred in the same place and on the same testicle, which Dr. Root treated by puncturing, and which healed up quickly. Concomitant with this attack of the epididymis, the patient had a perineal abscess, which quickly healed up. Neither abscess was, apparently, accompanied by any gonorrheal discharge. In 1894, at or about the time that he had his periproctic abscess, he had another swelling in his perineum, which was opened and which healed up kindly. This perineal abscess had no connection with the urethra, and at the time of my visit to him, on January 16, 1895, had apparently healed up, for the only lesion that he had was this periproctic abscess which had formed in the latter part of 1894, about two months before I saw him. On inquiring into his sexual habits, I learned that for thirteen months previously he had had no sexual intercourse, and on examination of his genitals no disease of any kind could be detected. He had had no abscess of the prostate, his bladder seemed to be in good condition; indeed, all his genitourinary apparatus seemed to be in working order. The thought occurred to both Dr. Root and myself that he might possibly be addicted to unnatural practices, and the question was asked as to whether he had ever practised pederasty, actively or passively, which he vehemently denied, nor did the anus show any evidences of unnatural practices. The anus was not relaxed or dilated, nor were the folds obliterated. No purulent discharge came from the rectum, the matter being entirely confined to the abscess around the anus.

Some of the pus was taken for examination, and it was believed by both of us that the result of this examination would reveal the presence of the tubercle bacillus. The report of the examination, however, made by Dr. Sondern on the 21st to the 25th

of January, showed it to be absent. The report is as follows:

Report No. 1242.

Pus from Periproctic Abscess.

Remarks: Staining for bacteria shows following results: Repeated search for tubercle bacilli by ordinary method (dried on cover glass) also sediment by v. Sehlen and centrifuge failed to reveal any.

Staining by Zeihl Neilsen and Ehrlich both repeated in 24-hour processes.

Gram's method shows numerous groups of pyogenic organisms (streptococci and staphylococci) in each specimen.

Staining by methylene blue shows numerous groups of gonococci which were decolorized by Gram's method, substantiating the view that they are Neisser's diplococci. These were repeated on account of unusual occurrence, considering the origin of the pus, with the same result.

Respectfully submitted,

(Signed) FREDERIC E. SONDERN.

The report surprised both Dr. Root and myself, for the last thing we suspected was the possibility of gonorrheal infection. In order to make perfectly sure that no mistake had been made, another specimen of the pus was collected on February 4, and this was examined between the 4th and the 8th, with the following report:

Report No. 1272.

Pus from Periproctic Abscess.

Remarks: Staining for bacteria shows following results: Regular cover glass dried specimen, as well as some of sediment by centrifuge. Staining by Zeihl Neilsen method, fails to show tubercle bacilli.

Culture on glycerine agar of specimen No. 1242 (first one examined) also shows negative results.

Gram's method shows numerous groups of pyogenic organisms, as in last specimen.

Staining by methylene blue, Eosin shows besides many eosinophilia, also some groups of diplococci, which I believe to be Neisser's and which are decolorized by Gram's method, which would tend to substantiate this view.

Respectfully submitted,

(Signed) FREDERIC E. SONDERN.

This latter report appeared to confirm the correctness of the previous one, and no further examinations were made, inasmuch as what had been done was deemed sufficient for the purpose, and the patient was put upon local treatment, the abscess being cleansed with a solution of hydrozone, and in the course of a month's treatment the abscess healed up entirely without any complications, except that on inquiring of Dr. Root as to the ultimate result, he told me that the abscess had destroyed a portion of both sphincter muscles, producing more or less incontinence of feces. In consequence of this statement, I obtained Dr. Root's permission to examine the patient, who very obligingly called upon me on March 14, 1905, and he confirmed the statements made above, and also afforded me an opportunity to examine his rectum. I found some slight loss of tissue on the right side, but not very much. The anus had a curious infundibuliform appearance, and was patulous. On the outside, and surrounding the anus entirely, were excrescences which resembled very much condylomata. This condition of affairs was evidently due to the loss of the external sphincter, and although there was some incontinence, it was more especially marked if the bowels were at all loose; if they were regular, and the stools were normal in size, he was able to retain his feces pretty well. In order to avoid accidents, however, he was obliged to wear a napkin. There was no evidence of any old fistulous track, and what ulceration there had been was entirely external, and not running up into the bowel at all.

I am well aware that this is a most extraordinary history; indeed, it is so extraordinary that I have not dared to publish it until the present time, and only do so now in order to place it on record in the hope that other similar cases may be reported and not leave this as a unique specimen of its kind.

Here we have practically a man who has been free from any gonorrheal attack for 6½ years. Three years after his last attack of gonorrhea he had an abscess of the epididymis associated with a perineal abscess, which apparently came on spontaneously; from that time until I saw him in 1895, 3½ years later, he had been in apparently perfect good health, I mean in a general sense. Then he is attacked with a periproctic abscess. Pederasty is denied, nor were any signs present which would warrant a belief that the patient falsified. This abscess was opened by Dr. Root, and the pus which exuded from it was abundant and apparently laudable. Two examinations of this pus revealed the presence of diplococci which presented all the morphological attributes of the gonococcus and which responded to the bacteriological tests peculiar to this bacterium. Where did these gonococci come from? Is it possible that the gonococcus may be retained in the tissues or in the circulation, to reappear in various portions of the body; or is there a diplococcus, which, to all intents and purposes, resembles the gonococcus in every way, and yet is not a gonococcus? I frankly confess I am unable to answer the question. As I have said, I simply report the case because it is such an extraordinary one—so unlike anything that I have ever seen or that I have been able to find after a careful review of the literature on the subject—and because I hope that similar cases may have happened in the experience of others, who may be disposed to report them. Certainly, the more closely I become acquainted with the gonococcus, the more disposed am I to regard it as a stumbling block unto the bacteriologist, and unto the clinician, foolishness.

16 WEST THIRTY-SECOND STREET.

THE CAUSE OF CEREBROSPINAL MENINGITIS.

BY STEPHEN J. MAHER, M.D.,

NEW HAVEN CONN.

THE pus from the spinal canal of a comatose adult, sick with cerebrospinal meningitis, was taken warm to the laboratory. A platinum loop brought up from the depths of the tube a thickened particle a third of an inch long and wide and an eighth of an inch thick. This fragment was used to inoculate tubes of sheep serum, human serum, milk, bouillon, and white of egg, and was then smeared over glass slides which were stained by Gram's, Wright's, Gabbett's, and Neisser's methods. To the original tube containing the spinal fluid, was then added an equal amount of sterile milk. The cultures were growing in the incubator within fifteen minutes of the time the pus had left the tossing body of the patient.

The smears gave beautiful pictures of the intracellular diplococcus of Weichselbaum. The organism was always of biscuit shape, and it decolorized with Gram. No other organism appeared in the direct smears from the pus. In direct smears taken from the sordes on the patient's teeth, I found many biscuit diplococci, a few lance-ended diplococci, and many bacilli, all of which stained with Gram. The rod was as long as an average Klebs-Loefler bacillus,

and often seemed a little more deeply stained at the poles. Unfortunately, I made no cultures from the sordes, and stained the direct smears only after the Gram and Gabbett methods.

On examining the cultures, fourteen hours later, I found nothing in the human-serum tube, nor in the white-of-egg tube, but in the other tubes, growths had begun. In the liquid media were only biscuit diplococci, but in the sheep serum there was a pure culture of a lance or blunt-ended diplococcus, often capsuled and often showing in each of its halves biscuit diplococcus. The conclusion that these pneumococci had been developed from the biscuit diplococci of the pus cells seemed inviting. The next day however, the blunt and lance shapes had almost disappeared, and later they did disappear entirely, leaving characteristic pure cultures of the Weichselbaum diplococcus. At the end of forty-eight hours, on the human serum there was a pronounced growth of the biscuit diplococcus on the surface and in the depths of the hard medium. This growth has not at any time contained rod or lancet shapes, but it resisted decolorizing more strongly than the diplococcus grown on sheep serum.

Subcultures, most of them from the tubes of sheep serum, were made at the end of twenty-four hours on various media. The resulting growths, except in two tubes of sheep serum, were characteristic pure cultures of the biscuit diplococcus or a slight admixture of the lancet diplococcus, which, in the course of a few days disappeared and left the field free to the biscuit shapes. Now as to the two excepted tubes. At first they seemed to contain no growth, and I took no smears from them, but on the sixth day, while looking through the basket containing them, I noticed a slight softening and an increase in the water of condensation, and I investigated. To my surprise, I found no biscuit diplococci, but apparently a pure culture of a rather large rod, a rod as large as *B. coli communis*. It decolorized by Gram. I satisfied myself that it could not be a contamination. By the usual methods, I made sure to get the organism in pure culture. It did not change litmus milk. It grew readily on ordinary media, developing ovoidal spores on agar, and lengthening out in milk into worm shapes, having at one almost pointed end a coccal granule of the size and shape of the meningococcus.

After a few days I injected two rabbits intraperitoneally with some of these rods taken from a poured agar plate and shaken up in bouillon. The rabbits had a slight increase of temperature for a couple of days, but, to my disgust, they soon showed only the symptoms of perfect health. After twelve days I killed one of the animals. The spleen looked large and rather gray, and the kidneys contained five little soft nodules, otherwise there was nothing abnormal. Direct smears from these nodules showed them to be made up of rather large lymphoid cells. No bacterial forms were discovered. I inoculated some tubes of sheep serum with this soft matter, and in fourteen hours I found a few granular rods not unlike the ones injected; and stranger still, after twenty-four hours more the serum was covered with creamy, isolated colonies that were made up entirely of a biscuit diplococcus that stained blue by Gabbett, orange with a black central point by Neisser, and did not decolorize by Gram. In subcultures on sheep serum, human serum, and agar the diplococci decolorized perfectly by Gram.

These findings were so surprising that I made very thorough search at the autopsy of the second rabbit which took place three days after the first. I found nothing abnormal except a small glistening pearl on the surface of the liver and a large, granular spleen. With sterile instruments I picked out the spleen and dropped it into a tube of milk, and made smears and cultures from the blood, the contents of the spinal canal, and the liver nodule. The direct smears revealed no bacteria. The liver nodule was made up of immense cells containing other bodies that suggested small yeast cells.

At the end of fourteen hours there was no change apparent in any of the tubes except in that containing the spleen. In this, the milk was entirely digested into a thin, reddish fluid surmounted by a mass of foam that reached almost to the cotton plug and that enwrapped the spleen. Smears showed the milk full of a bacillus morphologically like the one injected into the rabbit fifteen days before.

Subcultures from this tube, on either solid or liquid media, gave in twenty-four hours invariably, except in the potato tube, no rods but either small lancet or biscuit diplococci that decolorized by Gram.

On potato, the growth was always of a blunt rod, many times longer than the diplococcus, but shorter and thicker than the forms found in the original spleen-milk tube, and divided transversely. After forty-eight hours the sheep-serum tubes inoculated from the spinal canal showed a pure culture of a rather lancet-ended diplococcus that decolorized with Gram.

The gross and microscopic appearance of colonies in poured agar plates is the same for the original bacillus injected into the rabbit and for the bacillus recovered from the spleen. Under the low power the deep colonies have at first egg shapes which later give off glistening irregular branchings.

One distinct difference that I found was in the power of changing milk. The original bacillus, as I have said already, neither curdled nor digested milk, whereas the bacillus planted from the spleen, or rather with the spleen, digested the milk and rendered it intensely acid. But as perhaps throwing some light on that point, I might add that the diplococcus fresh from the patient's pus, had the power of curdling milk, a power that it lost gradually by subculturing.

In looking over the old tubes to-day, seven weeks after the first plantings, I find that in the original cultures from the spinal pus there remain only biscuit diplococci, a few of which have swollen almost to the size of yeast cells; that in the blood-serum tubes in which the rods were first discovered there are still fine rods in pure culture but of differing lengths, some empty, some entirely stained, and some showing contained biscuit diplococci at poles or centers; that in a tube of incubated sugar gelatin the original bacillus has grown into great coils of lines like those in a yeast film; and finally that in the litmus milk planted with the original rod and for a long time containing only that rod, there are now, besides the rod, many small clumps of biscuit diplococci.

In the epidemic of queer sore throats that we had in New Haven at the same time as our visitation of cerebrospinal meningitis, besides finding the biscuit diplococcus and the pneumococcus, I have been interested to see that in a large proportion of my cases, there were, in the direct smears from the tonsils or pharynx clumps of *Saccharomyces cerevisiæ* or some similar yeast, and rods similar to those that I injected into the rabbits. I have not worked this point out thoroughly, but as a result of my efforts to get pure cultures of the yeasts and the bacilli and the diplococci, I find myself drifting to the conclusion that the yeasts may break up into rods and the rods into coccal or diplococcal forms, and that the yeasts may again be formed by the swelling of individual cocci.

He would be daring who would generalize on so large a subject from his work on one case, but may I

be permitted to conclude by saying that my findings seem to show that the diplococcus of Weichselbaum is only one phase in the life cycle of an organism, which at times is larger and rod shaped, at others small and of the shape of the pneumonia diplococcus, and probably at others of yeast shape.

213 Orange Street.

PRIMARY EPITHELIOMA OF THE EPIGLOTTIS.

By D. BRYSON DELAVAN, M.D.,
NEW YORK.

Mr. X, aged 62, was brought to me in consultation early in December, 1902. At that time there appeared upon the left side of the posterior (laryngeal) face of the epiglottis an area of hyperemia about a quarter of an inch in diameter and circular in shape. The color of this area was only slightly deeper than that of the surrounding tissue, but its edges were sharply defined and it appeared to be faintly elevated.

During several months subsequent to this the congestion steadily increased and the elevation became more pronounced; the area of the base, however, remained limited to about its original dimensions. As the condition advanced it became evident that it probably indicated the beginning of a new growth upon the epiglottis. Meanwhile the central part of the elevation became slightly depressed and yellowish in color and the appearance assumed more and more that of a definite neoplasm.

In June, 1903, the patient was again seen and the condition found to have assumed such definite characteristics that the diagnosis epithelioma was hazarded and the excision of the diseased area was advised. As the patient was about to go abroad, and expected to spend the summer near Vienna, where he was well acquainted, he determined to be operated upon there. Before his departure the question of an extensive removal of the parts adjacent to the growth was discussed and radical operation was objected to, first, because the patient was in feeble health, a man of intensely nervous temperament and one not likely to resist well the shock of an extensive operation upon the larynx or to endure with success the conditions attending convalescence. Moreover, it appeared possible that the removal of the diseased area itself might be sufficient to effect a cure, as there was no evidence visible that any extension of the disease had taken place.

On reaching Vienna, June 22, 1903, the patient at once placed himself under the care of Privat-Docent M. Hajek who fully concurred with the opinions expressed above and excised a small fragment of the growth for microscopical examination. This was sent to the pathological department of the University of Vienna, which reported that the specimen showed epithelioma. During the course of the week which followed the slight operation for the removal of the above-mentioned specimen the progress of the growth which had hitherto been very slow became so rapid that immediate operation was insisted upon. Accordingly, about one-third of the epiglottis was removed, including the diseased area. The operation was a very simple one, accomplished at two sittings under cocaine anesthesia, with the aid of Hermann Krause's laryngeal cutting forceps. It was attended with no bleeding or other feature of note excepting slight dysphagia for two days, and was followed by prompt recovery. At no time since has any difficulty in swallowing been experienced.

Microscopical examination of the excised fragments again showed the presence of epithelioma, the disease involving all of the structures from the surface of the mucous membrane down to the cartilage. Its superficial extent, however, was clearly limited, so that its complete removal by the operation seemed to have been successfully accomplished. The patient again reported to me in October, 1903. Healing had quickly followed the removal of the growth and the parts, save for the loss of the substance of about one-third of the epiglottis, appeared to be in normal condition. It has continued so up to the present time, without the slightest indication of any extension or recurrence of the trouble, the patient meanwhile being in excellent general health.

This case presents several points of unusual interest:

1. Epithelioma of the epiglottis is of very rare occurrence.

2. In this case the disease was studied from its earliest inception and it was possible to note the progress of the growth from one stage to another until almost up to the time when ulceration might have been expected to take place.

3. The limitation of the area of the growth was a matter of interest. For a long while there was not the slightest tendency apparent for it to spread beyond the original limits of its base.

4. The occurrence of the growth upon an organ composed of soft tissue and cartilage, originating near the margin of the organ and in such a position as to make possible its complete and thorough removal.

5. The striking change which took place in the rate of progress of the growth after the removal of the first specimen for examination.

6. The failure of recurrence to have manifested itself after a period of nearly two years.

Several of the same phenomena observed in this case have been seen not infrequently in cases of epithelioma in other parts of the body, notably in the helix of the ear, a structure somewhat similar anatomically to the epiglottis, where simple excision of a small epitheliomatous growth has often effected permanent cure. The study of these and analogous cases suggests an important deduction with regard to intrinsic carcinoma of the larynx, namely, that in certain localities of the body early involvement of the lymphatic system does not seem to be a necessary occurrence. In consequence of this complete early excision of the diseased area may be followed by permanent cure. Clinically, the practical application of this theory to intralaryngeal carcinoma has often resulted in success. It is fair to believe, therefore, that intrinsic laryngeal carcinoma, recognized early and early removed, may be fairly considered a remediable condition. This proposition, in fact, has been abundantly proved by the experience of many surgeons during the past fifteen years. The report of the case herein quoted, however, is made worth while as being corroborative of it, as well as by the very unusual character of the case itself.

1 East Thirty-third Street.

Mucous Colitis.—De Wolf says that of the many drugs tried for this condition, the only ones he has thought were of benefit were castor oil and salol, five minims and gr. ii, in a capsule, three or four times a day. Given over a long period (if they do not disturb the stomach) they have seemed to play some part in lessening the amount of mucous discharges. More valuable than any one factor, however, is the persistent use of high enemata, hot water or better normal saline, once or twice daily. This should be taken on the back or side, with a rectal tube, one pint at a time, the injection being used twice. The first pint brings away fecal matter and some mucus; the second pint, clear mucus and often in large quantities. The enemata should be continued for at least two weeks after the disappearance of the mucus.—*Providence Medical Journal.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, May 6, 1905.

THE ETIOLOGY OF CANCER.

AN interesting debate on cancer was recently held in the Berlin Medical Society, several evenings being occupied with the discussion of this important subject. Orth read the first paper, entitled "The Morphology of Cancer and the Parasitic Theory." He said that many of those who had announced alleged important discussions regarding the etiology of malignant growths, had often ignored the all-essential anatomical facts. Cancers are epitheliomas because they are composed chiefly of epithelial cells, but not all epitheliomas are cancers. The cells of the metastases resemble, although not always completely, the cells of the primary tumor. This fact, Orth maintains, affords positive proof that the metastatic cells have their origin in the primary tumor. While tubercles need bacilli for their development, cancer metastases need cancer cells for their growth. The experiments to produce cancer in animals prove only the possibility of a transplantation of cancer tissue analogous to Thiersch's skin transplantation. He who believes that parasites cause cancer, ought to be able to prove that a tissue without the specific cells can produce cancer, and he should be able to produce the parasites characteristic of the different varieties of malignant growth. Orth concluded by saying that he was not an adversary of the parasitic theory, but before he could accept it he must require more convincing proof than had yet been offered by its advocates.

Hansemann read the second paper entitled "What Do We Know Concerning the Etiology of Cancer?" He stated that there are three theories current in the literature as to the origin of cancer: (1) The theory of infection; (2) the theory of heredity, and (3) the traumatic theory. The theory of infection is the oldest and is based on (*a*) inoculation experiments; (*b*) clinical observations; (*c*) statistics, and (*d*) parasites. Hansemann has for many years performed experimental inoculations but without success. It is not sufficient for a tumor to develop after an inoculation with microscopical material, but this must be followed by the development of a true cancer and cachexia. The so-called successful experiments which have been reported of transferring infection from animal to animal of the same kind, are not examples of infection, that is of the transference of infectious germs, but they are pure transplantations. The implanted tumor is surrounded and penetrated by inflammatory tissue, and is nourished in this way; but the new tumor is limited in its growth and gives rise to no metastases. Clinical observations are said to be an evidence of the parasitic theory, because of the reported occurrence of epidemics of cancer, but such are merely chance occurrences, as in the case of a married couple both suffering from cancer. It may also happen that husband and wife both suffer with gout or diabetes, diseases more rare than cancer. As to the fact that statistics prove that the death-rate of cancer is increasing, the speaker said that this might be due to the fact that many people used to die before the cancer age, from diseases which were formerly not under such good control as they are now, such as diphtheria. Debovy has demonstrated that the increase concerns only internal cancers, and that the prevalence of skin cancers has remained stationary. It is not necessary then to be alarmed on account of these reports. As to the protozoan theory, it must be remembered that little is known concerning these organisms. The case is parallel with that of bacteria. The disease in rabbits caused by coccidia has no tumor formation, and the affection of the bladder by bilharzia is preceded by a chronic inflammation of this organ, so that the lesions are not caused directly by this microorganism. Those who are convinced that parasites are the cause of cancer, ought to be able to prove that this is true. The speaker was not convinced that any one of the parasites which have been described as being the cause of cancer is the real cause. Those who believe in the theory of heredity are obliged to depend upon the uncertain statement of the patients, and the still more uncertain transmission. The medical history of the Bonaparte family, for example, is always quoted in support of this theory. But this family has remained free from cancer, with the exception of the great Napoleon and his father, both of whom suffered from this disease. If cancer were inherited, then it should be possible to find cancerous degenerated teratomata which are congenital tumors. But such a condition is never observed. However, Hansemann admitted that the disposition for the development of cancer might be inherited.

As to the traumatic theory, the speaker said that acute trauma did not produce cancer, but was capable of making the disease worse, or of attracting attention to a cancer already established. Chronic traumata doubtless assist in the development of cancer, for we know that cancer favors localities in which traumata most usually occur. No one of the three theories covers all kinds of cancer. The one accepted fact is that declared by Virchow that cancer and all other tumors originate from the combined effect of an irritation and a special susceptibility in the patient. What this irritation is we do not yet know.

The most noteworthy contribution to the discussion was that of v. Leyden, not because this eminent clinician demonstrated the parasitic nature of cancer, but because of his frank avowal of a firm belief in the truth of the parasitic theory. He drew entirely different conclusions from those of the pathologists, and declared his conviction that cancer was an eminently infectious disease. When an individual who formerly was quite well, suddenly falls ill with cancer, quickly declining, and when the internal organs are affected through the lymphatics, then the physician must admit that cancer is a parasitic disease. He presented several facts as evidence of his opinion. The first argument was drawn from animals, cancer being found in those only which are associated with man—the dog, cat, horse, ox, mouse,

and rat—and among these the most frequently attacked are those living near laboratories or post-mortem rooms. Very rarely or never are wild animals affected. Several localities, such as the antarctic region, are free from cancer. Cancer was unknown among the negro tribes in Africa until they came in contact with the whites, but now, in America, the negro is often attacked by this disease. The number of cases in large towns is on the increase, and several epidemics in smaller places have been reported. Such an occurrence should not be attributed to chance, he said, when we are not able to prove it. The parasitic theory must suggest itself when it is observed that those parts most frequently attacked are such as are accessible from without, such, for example, as the tongue, larynx, intestine, lungs, vagina, and skin.

Of the greatest importance are the cancer implantations of Dagonet, who performed these experiments on rats, and the implantations from man to man. Van Bergmann saw a case of cancer of the lip, manifestly due to contact. These transferred tumors gave rise to metastases. Now, when a disease is transmitted by means of living cells, we call it infection, and, therefore, the transmission of cancer from one individual to another by means of cancer cells is an infection. Michaelis was able to transmit cancer in mice in 50 per cent. of all cases. There is unquestionably a decided characteristic of election in the cancer parasite, because the implantation does not always succeed. But the fact that transplantation is possible and the constant aptitude of cancer to give rise to metastases, proves that the cells are infectious. The bacteria which have been hitherto described are justly rejected, but v. Leyden himself has found cell inclusions which he believed to be the cancer parasite. Other investigators have taken them for degenerated leucocytes or vacuoles, but they are very distinct from these. The speaker thought that probably, but not certainly, these cell inclusions belong to the class of protozoa. The researches of Blumenthal, Bergell, and Wolff, he said, support the parasitic theory. By chemical investigations they proved that cancerous tissue contains more albumin and less globulin than all other organic tissues, and they had succeeded in producing a ferment which decomposed not only the cancer albumin but also the albumin of all other tissues, while elsewhere the single tissue ferment decomposed only its own special albumin.

Olshausen and Benda, the pathologist, also upheld this theory for the not very scientific reason that none of the others offered a sufficient explanation. Benda did not think, however, that the fear of cancer was justified, even if the disease was caused by parasites, because there was a difference between contagion and parasitic transference. Endocarditis, trichinosis, malaria, and leprosy were parasitic diseases, but they could scarcely be called infectious ones. O. Israel contested the possibility of a parasite. He assumed that the tumors grow because the body offers an abundance of material for them. Parasites are not necessary for this. Besides, a cell itself containing a living parasite never divides; either the cell or the parasite perishes. B. Fränkel stated that as long as the true etiology was unknown, individuals should not be exposed to the possibility of infection. He said that it was well known that benign tumors could be infectious.

It is interesting to learn the conflicting views of these well-known Berlin pathologists and clinicians and to hear the arguments with which each one endeavors to defend his position, but we cannot see that the discussion has brought us any nearer the longed-for solution of the problem. We would fain believe with v. Leyden that malignant neoplasms are of parasitic origin, for the demonstration of that as a fact would inspire to greater therapeutic efforts, but it must be admitted that the weight of scientific opinion is as yet adverse to this theory.

THE CARE OF RESPIRATION IN INFANCY AND CHILDHOOD.

The *British Journal of Children's Diseases* for April, 1905, publishes two lectures on this subject delivered at St. George's Hospital by Dr. William Ewart. These lectures enter fully into what the speaker terms respiratory pediatrics. The practical object of respiratory pediatrics is defined as an improved knowledge (1) of the causes and mechanism of the various respiratory defects; (2) of the means of preventing the latter or the diseases which produce them; and (3) of the methods best calculated to cure or correct them. Gastrointestinal affections are most prevalent during the first eighteen months of life, but when the child begins to stand and walk, complaints of the respiratory system prevail, together with the "civilization disease" of infancy—rickets.

Referring to the medical supervision of infancy and childhood and its opportunities, Dr. Ewart says that the whole of pediatrics is governed by the central fact that the disorders to be treated occur during the stage of rapid growth of the organism, and this has two important aspects: (1) The tender age of the individuals renders them peculiarly susceptible to the damaging effects of disease, and makes more stringent our duty to protect them: (2) The *vis medicatrix,* inherent to the most active periods of growth lends considerable assistance to any suitable curative methods that we may adopt. A synopsis of the chief respiratory affections to which the child is subject is then given, after which the author deals with the infantile chest, infantile respiration, thoracic deformities, and some of the pulmonary lesions due to infantile or puerile diseases. Attention is drawn to the fact that chief among the so-called "trivial" ailments of childhood are the obstructive affections of the pharynx, nose, and nasopharynx, and, as it seems, the increasingly frequent evils of overgrowth of tonsils and adenoid tissue. The duty of the pediatric physician in this connection is sketched as follows: (1) Prevention is obviously the first indication. It will never cease to be the pediatrist's duty to try to forestall this evil until he shall have finally succeeded. Unfortunately we have not yet even cleared up the mystery of its origin. Timely treatment is a special indication in all affections liable to have sequelæ; and for that purpose the first essential is early diagnosis. The writer urges that in the future a study of adenoids in infants should be made before the condition is established. In other words, one should examine infants from the point of view of their future liability. Babies with narrow air-passages and thick mucous membranes are not unlikely to be the future sufferers from adenoids. After-treatment is the next task before the pediatrist, and it should not be too long delayed, as then it may not be completely suc-

cessful. The removal of the overgrowths often comes rather late, and not in time to obviate the deformity, or the deafness, or the backwardness; but perhaps even then a more assiduous after-treatment might produce a greater effect. This means that when the obstruction has been removed one must not shrink from the trouble of a systematic reeducation on the lines laid down by Desgrange, Rosenthal, Harry Campbell, and many others. Already laudable efforts have been made to cure the evil of mouth-breathing; but much remains to be done in this direction and in that of defective articulation, and also in the teaching of free and deep breathing.

The remainder of the lecture is devoted to a consideration of the infantile chest, of the normal type of infantile respiration, of the respiratory function of the spine in infancy and childhood, of the inspiratory forces, of the expiratory forces, of abdominal respiration, and of the puerile type of respiration.

In reference to the art of breathing, Dr. Ewart says that awkwardness of breathing or faulty breathing prevails more largely in large towns than among the country population because of the greater prevalence of adenoid affections. Therefore, in towns pathological types of respiration have to be unlearned and physiological breathing has to be taught like a lost art. For this a first essential is the systematic inspection of all children by highly competent observers, capable of recognizing, not only manifest cases where chest deformity coincides with faulty function, but also those less advanced where the latter tends to bring about insidiously pulmonary as well as thoracic impairment. This is said to be, in civilized countries, an age of physical deterioration, and particularly so in those countries whose population is chiefly centered in large towns. That town life under the conditions in which the bulk of the people live does not tend to physical advancement, is obvious, and indeed the manner in which the inhabitants of civilized lands are massed together in towns is one of the most serious problems of the times. There can be no doubt that respiratory efficiency is an essential factor in the development of a healthy body, and further that such efficiency is sadly lacking in the young population of present day towns. Dr. Ewart's advice, therefore, that proper breathing should be taught to children, and respiratory defects of all kinds among the young should be remedied as far as is possible, is timely and pertinent.

Lupus Pernio.

Besnier was the first to describe a peculiar rare form of lupus, limited usually to the nose, ears, and hands, but affecting at times also the feet or other parts. Kreibich in the *Archiv für Dermatologie und Syphilis*, LXXI, in reporting three instances of the affection, gives a good description of the onset with diffuse somewhat raised spots, at first red, but changing to reddish blue. Infiltrated areas of pin-head size project above the surface in the form of papules of brownish yellow hue. Upon the hands the dorsal surface of the fingers are mostly involved in a deep bluish red infiltration, consisting of epithelioid cells. This marks the histological distinction from the lupus vulgaris infiltration, which shows a peripheric infiltration of round cells, making the limitation of the papule or tubercle from the surrounding connective tissue indistinct. The foci, which are located for the most part above the deeper vascular network, contain capillary vessels about their periphery and center. Tubercle bacilli have not been found, and the author uses this as an argument against the affection being in reality a lupus; a further point against which is that no reaction follows the use of tuberculin. He would, however, retain the name and group it along with the indurated erythema among the cutaneous tuberculoses.

The Price is Too High.

Assemblyman Hackett from this city has introduced a bill in the Legislature providing for the erection of a 700-bed public hospital on the West Side of New York City, between Twentieth and Forty-second streets. We trust the bill will be promptly killed either by adverse votes in the Assembly, or by the Governor's veto. This is not because a city hospital in that part of the town will not be of service, but because the bill provides that the institution shall be under the control of the Commissioner of Public Charities. The experiment was made two or three years ago of taking the control of the public hospitals away from the Charity Commissioner and giving it to a special board of "Trustees of Bellevue and Allied Hospitals." This board, under the most efficient leadership of Dr. John W. Brannan, has done excellent service and it is the universal testimony of those best fitted to judge, that the hospitals were never better managed. No new public hospital should be established that is not to be under the same control. This is not to be taken as a reflection upon the present Commissioner of Charities, who is a capable public official, and is, himself, a member of the board of trustees of the city hospitals. It is simply that we would protest against this opening wedge for a return to the old and most vicious system of hospital management that formerly prevailed in New York City. The price which Assemblyman Hackett asks for his new hospital is too high.

News of the Week.

Medical and Chirurgical Faculty of Maryland.—At the 107th annual meeting of this society in Baltimore, April 25-27, Dr. William Osler delivered an address on "Unity, Peace, and Concord," in which he depicted the potent influence of these essentials when practiced by the medical profession, not alone upon the members of the latter but more especially for the good of suffering humanity. He dwelt specially upon "charitableness among physicians." An address on the "Physiological Basis and Clinical Effects of Hydrotherapy in Chronic Disorders," was delivered by invitation, by Dr. Simon Baruch of New York. Prof. Clarence Blake of Harvard, addressed the members on "Uniformity of Medical Education," advocating the consolidation of medical colleges, which would inure to the benefit of students, physicians, and the public, and giving an excellent historical sketch of American colleges in the early days of our history. At a farewell dinner given to Dr. Osler at the Stafford House, on the evening of April 28, the Governor of the State and the Mayor of Baltimore spoke approvingly of the action taken by the faculty, with regard to building a complete system of sewers by the city. Governor Warfield, in a spirited after-dinner speech, expressed the regret of all in the loss of Dr. Osler. He referred to the Osler joke, and its dire results, and related a somewhat similar misfortune that had befallen him. "It was my misfortune," he said, "to advise some young women graduates in an address, not to marry early. I did not and could not advise them at what age to marry, but jestingly told them that my wife married at the age of 26. Immediately

the newspapers charged me with advising girls to wait until the twenty-sixth year before marrying. Small wonder that when the newspapers twisted my meaning all the girls were down on me, just as all the old men are down on Dr. Osler. I have a fellow feeling for him now."

The Plague in South America.—Since the year 1903, when the bubonic plague first made its appearance on the west coast of South America, it has never entirely disappeared. During this year there seems to have been a recrudescence, particularly in the southern part. In March it began in Mollands, the port of Avequipa, Peru. In Lima there are one or more cases discovered daily. Though the type of the epidemic seems to be comparatively mild and not extremely contagious, nevertheless it continues. Should it get a footing in the interior of the country, it would probably be more fatal than on the Coast, as the hygienic habits of the population there are worse than those of the Coast. The disease has made terrible ravages at Pisagua, Chile, and refugees from that town assert that for some time before their departure the deaths there had ranged from ten to thirty a day, and the authorities were then unable to enforce burials. Bodies were thrown into the streets and spread contagion. But little headway had been made in the fight on the disease, and it seemed as though the entire population of that Chilean port might be exterminated by the plague. Many persons had been shot down by the soldiers on guard while attempting to escape from the stricken city.

Meningitis in Germany.—It appears that the disease is still spreading, and cases are now reported from all parts of the empire. The greatest number continue to come from the mining districts in the East, such as Breslau, Essen, Kattowitz and Brunswick. Troops that had been sent from the affected districts are being recalled to them in order to restrict the spread of the infection. In the district of Kattowitz there have already occurred 358 cases, with 203 deaths.

The Finsen Memorial Fund.—The committee authorized to receive subscriptions in America for the Niels Finsen Memorial Fund desires to announce that the collections will be closed in this country by the 1st of June next. Those desirous of contributing to a fitting memorial to the last distinguished Norwegian scientist, may send their contributions to Dr. James Nevins Hyde, 100 State street, Chicago, Ill.

Banquet to the Medical Members of the Missouri Legislature.—The St. Louis Medical Society and the Medical Society of City Hospital Alumni of St. Louis will give a complimentary banquet to the medical members of the General Assembly of Missouri on Wednesday, May 6. The banquet is given in recognition of the services of the guests to the public and to the profession in securing legislation for the establishment of a State sanatorium for consumptives, Missouri being the ninth State to appropriate public funds for this purpose.

Abolishment of the Visitation Boards of the State Hospitals.—The New York State Assembly on April 26 passed the bill of Senator Allds abolishing the State boards of visitation of the State hospitals, and restoring the local boards of management for the individual institutions. These local boards will be of seven members each, two of them women, and are to be appointed by the Governor.

The American Roentgen Ray Society.—The sixth annual meeting of this society will be held at Johns Hopkins University, Baltimore, September 28, 29, and 30, under the presidency of Dr. Charles Lester Leonard of Philadelphia. The papers of the meeting for the first day will deal with *x*-ray diagnosis, and those of the second and third day will be therapeutic. There will also be an evening exhibit of lantern slides. The Belvedere Hotel has been selected as headquarters. The secretary of the society is Dr. Russell H. Boggs, Empire Building, Pittsburg, Pa.

The Société Internationale de la Tuberculose, the object of which is to study the most efficacious means of defense against and treatment of tuberculosis, held its general annual meeting in Paris on March 14, under the presidency of M. Richelot, member of the French Academy of Medicine. After a discourse by Dr. Samuel Bernheim, in which he clearly set forth the actual state of the question, the society proceeded to the election of the following officers: *President,* Professor Lancereau of Paris; *Vice-Presidents,* MM. Huchard, Richelot and S. Bernheim of Paris; Professor von Schrötter of Vienna; Sir Hermann Weber of London, and Professor de Lancaster of Lisbon; *General Secretaries,* M. George Petit, 51 Rue de Roches, Paris, and Count Ivan Toluiswski, 9 Claverly Grove, West Finchburg, N., London; *Treasurer,* M. Papillon of Paris.

American Gastro-Enterological Association.—The eighth annual meeting of this society was held in this city on April 24 and 25. The officers elected were: *President,* Dr. H. W. Bettmann of Cincinnati; *Vice-Presidents,* Drs. S. W. Lambert of New York, and John P. Sawyer of Cleveland; *Secretary* and *Treasurer,* Dr. Charles D. Aaron of Detroit.

The American Antituberculosis League.—On the final day of the meeting of this association in Atlanta, it was decided to hold the next annual meeting in El Paso, Tex. The officers elected for the coming year are: *President,* R. E. Conniff, Sioux City, Iowa; *Secretary* and *Treasurer,* Dr. Walter N. Vilas, of El Paso, Tex.; *Vice-Presidents,* Drs. Hubbard of Georgia, Van Dyke of Georgia, Ambler of North Carolina, Snodgrass of Missouri, McGhee of Louisiana, Milliken of Ohio, Hickey of Michigan, Williams of Kentucky, Porter of Florida, Gray of New Jersey, and McMurray of Tennessee.

Mississippi State Medical Society.—The following officers were elected at the meeting of this society held in Jackson: *President,* Dr. E. H. Martin, Clarksdale; *Vice-Presidents,* Drs. R. A. Seal, Holly Springs; W. W. Crawford, Hattiesburg; Stephen Eggleston, Greenwood; *Secretary,* Dr. L. T. Fox, Water Valley; *Councilors,* Dr. H. L. Sutherland, Rosedale; Dr. R. S. Currie, Columbus; W. D. Smith, Meadville; Wm. Neville, McComb City. *Delegates to the American Medical Association,* Drs. D. J. Williams of Ellisville and W. H. Harrison of Tutwiler.

Lincoln County (Mo.) Medical Society.—The physicians of this county have organized a society with the following officers: *President,* Dr. S. R. McKoy of Troy; *Vice-President,* Dr. Strickland of Moscow Mills; *Secretary* and *Treasurer,* Dr. W. P. Smith of Troy.

Hartford County Medical Association.—At the 113th annual meeting of this society held in Hartford, the following officers were elected: *President,* Theodore G. Wright of New Britain; *Vice-President,* Dr. G. P. Davis of Hartford; *Clerk,* Dr. E. R. Lampson of Hartford; *Censors,* Drs. Robert M. Clark of New Britain, Oliver C. Smith and Thomas F. Kane of Hartford; *County Reporter,* Dr. Kenneth E. Kellogg of New Britain; *Alternate,* Dr. Michael A. Bailey of Hartford. *County Dissertator,* Edward L. Whittemore of New Britain; *Alternate,* Arthur S. Brackett of Bristol.

Prof. Roentgen's Shyness.—A striking instance of the modesty of genius, was afforded on the occasion

of the recent *x*-ray Congress in Berlin. The congress opened on April 29, and the feature of the meeting was to be the presence of Prof. Roentgen who, it was announced, had accepted the invitation of the practitioners of this new science who wished to do him honor. But, despite his promise, and although his name was on the programme, when the time came he declared he simply could not attend the sessions, as it would be impossible for him to face the crowd which had gathered to glorify his work. Consequently, the professor merely telegraphed his acknowledgments from Wuerzburg, much to the disappointment of the assembled radiologists.

Farewell Dinner to Dr. Osler.—About five hundred physicians from the Eastern States and Canada dined at the Waldorf-Astoria Hotel in this city, on May 2, to do honor to Dr. Osler before his departure for England. The toastmaster was Dr. James Tyson of Philadelphia, and the list of speakers and of the toasts to which they responded was: Dr. Osler in Montreal, "Student and Teacher," Dr. F. J. Shepherd of Montreal; Dr. Osler in Philadelphia, "Teacher and Clinician," Dr. J. C. Wilson of Philadelphia; Dr. Osler in Baltimore, "Teacher and Consultant," Dr. W. H. Welch of Baltimore; Dr. Osler, "The Author and Physician," Dr. A. Jacobi of New York City; presentation of "Cicero de Senectute," by Dr. S. Weir Mitchell of Philadelphia. In presenting a beautifully bound copy of James Long's translation of "De Senectute," in the edition printed by Benjamin Franklin at Philadelphia in 1744, Dr. Mitchell said: "Cicero must be regarded as an anticipatory plagiarist, for he said in one place that 'it is desirable for a man to expire at the right time.' What humorist selected the gift I don't know, nor do I know what sarcastic genius singled me out to present it. But I suppose my own fitness depended on the fact that I am the youngest man here tonight, and thus best suited to bring the homage of youth to our venerable friend, the Regius Professor. If Cicero had been more scientific in the modern sense of the word, he would have been less vague as to what decade should call us hence." Dr. Osler replied fittingly to the words of praise and expounded again his three ideals or rules of conduct: to do the day's work well and not to think of to-morrow, to follow the golden rule, and to cultivate a certain measure of equanimity. The programme printed for the evening bore on its middle page a fine picture of the guest of honor. The souvenirs of the occasion were small apothecary's mortars, in which the ice-cream was served, and, accompanying them, miniature porcelain pestles.

New State Department of Health for Pennsylvania.—Governor Pennypacker has signed the bill passed by the Legislature at its recent session abolishing the State Board of Health and establishing in its stead a Department of Health whose head shall be clothed with almost unlimited authority in safeguarding sanitary conditions in the State. The Commissioner of Health contemplated by the new act must be a physician of at least ten years' experience and he is to receive an annual salary of $10,000. He shall he aided by an advisory board of six members appointed by the Governor, four of whom shall be physicans and one a civil engineer, to serve without salary, the State, however, paying their necessary expenses. The State shall be divided into ten health districts, each in charge of a physician of at least five years' experience, who shall receive an annual salary of $2,500.

Increase of Typhoid Fever in Philadelphia.—For the week ended April 29, there were reported to the Philadelphia Board of Health 289 cases of typhoid fever, with 20 deaths, as compared with 149 cases and 19 deaths for the preceding week. Most of the cases came from wards receiving their supply of water directly from the Delaware River, while the smallest number were from wards supplied with filtered water.

A Section on Medical History of the College of Physicians of Philadelphia has been formed and held its first meeting on April 24. Dr. Roland G. Curtin, Chairman of the Section, read a paper entitled "Esculapian and Modern Health Resorts Compared." Dr. William Pepper showed "Lantern Slides Illustrating the Early History of the Medical Department of the University of Pennsylvania." Dr A. Jacobi read a paper entitled "The Most Eminent American Physician of European Birth."

Licensing of Prostitution.—The Philadelphia Grand Jury for April in its final presentment made the recommendation that prostitution be licensed within prescribed limits under the supervision of the Board of Health. Judge Willson, to whom the presentment was made, expressed disagreement with the recommendation.

Bill to License Dentistry Vetoed.—The Governor of Pennsylvania has vetoed a bill passed by the State Legislature prohibiting the practice of dentistry by unlicensed persons, and prescribing a penalty of $500 or six months' imprisonment for its violation. He takes the ground that such offences are not crimes and should not be punished by imprisonment.

Smallpox in Chicago.—There were 93 cases of this disease at the Isolation Hospital, Chicago, on Saturdays of last week, that being the largest number of victims of this disease which the city has had on its hands in one day for ten years, since the epidemic of 1895.

Dr. L. Pierce Clark of New York has been appointed consulting neurologist to the Craig Colony for Epileptics.

Dr. L. H. Callaway of Nevada, Mo., has been appointed superintendent of the State Hospital for the Insane at Nevada, Mo., and Dr. Unterberg of St. Louis has been appointed specialist on diseases of the mind and nervous system.

Obituary Notes.—Dr. William Edwards, superintendent of the Michigan Asylum for the Insane, died on April 26 at the University of Michigan Hospital at Ann Arbor of heart trouble. Dr. Edwards was born near Peru, Ind., in 1856, and graduated from the University of Michigan Medical Department in 1884, and was that year appointed to the staff of the Michigan Asylum. In 1891 he was appointed superintendent.

Dr. Adolph Hoffman, of Chicago, a member of the faculty at the Jenner Medical College, died at his home in Oak Park on April 13. Dr. Hoffman was forty-three years old, and was graduated from the Jenner Medical College in 1897.

Dr. Ross Van Meter, of Greensburg, Ky., died on April 17 after a short illness. He was a graduate of the Miami Medical College, Cincinnati, in 1895.

Dr. A. L. Brown, of Springfield, Mass., died April 22 of pneumonia at the age of forty years. He was a graduate of the Medical Department of Howard University, Washington, in 1894. He was a member of the Springfield Board of Health.

Dr. Byron De Witt died at his home, in Oswego, N. Y., April 18, at the age of 78 years. He was born at Aurelius, N. Y., in 1826, and was graduated from the Medical Department of the University of Buffalo in the class of 1849. He was a surgeon in the Union Army during the civil war and had practised in Oswego since 1864.

Correspondence.

BLEEDING IN CEREBROSPINAL MENINGITIS.

To the Editor of the Medical Record:

Sir: In January, 1864, while residing in Glover, Orleans county, Vermont, I saw my first case of "spotted fever." The eruption was unmistakable, many spots petechial in character. The whole picture of the case was clean cut. I had two able medical men in consultation. A few days later I saw my second case and called two other prominent physicians to advise me. I was treating the cases on general principles. My treatment was fully endorsed by all of my advisers, and not a suggestion was made. Both cases, occurring in young women of about eighteen years of age, were fatal. I studied these cases, read standard works, and decided upon a line of treatment for the future.

I was called to see my third case on February 5, 1864. A young girl of nine years was taken ill in school, with vomiting, violent headache, passing rapidly into unconsciousness. In short, the symptoms were typical. I first saw the patient three or four hours after the invasion. She was unconscious. It at once proceeded to bleed from the arm, a practice almost, if not entirely, out of date at that time, and took at least a half pint of blood. As the blood flowed (my patient being supported in a sitting posture) the perspiration broke out on her forehead, intelligence shone in her eyes, she answered questions correctly, and the bleeding was at once discontinued. This was about eight o'clock in the evening. Some six hours later, there having been a gradual return of the brain symptoms, I decided to bleed again, but before I got ready she was fully unconscious. The patient being supported in the sitting posture I bled from the other arm until consciousness returned, taking another eight ounces of blood. The intellect remained dull for some hours after the second bleeding, but gradually cleared up in the course of the day.

The first bleeding was followed with aconite internally, steaming of the body and ice-water to the head, keeping up a free perspiration continuously night and day for a few days, with calomel and salts early and repeated, according to the indications. This child was out of danger on the fourth day, convalescent the eighth day, and dismissed, cured, on the twenty-third day.

The steaming was effected as follows: Ten common red clay bricks were heated in the fire. Then, one by one, they were immersed in a pan of boiling water until saturated, as evidenced by the cessation of air bubbles arising. Each was then wrapped in several thicknesses of cotton cloth wrung out of boiling water, and then wrapped in a dry towel, and six to eight were placed in the bed around the patient, beginning at the feet, the number varying according to the size of the patient. The reserve bricks were always in readiness, as was the boiling water, to replace a brick when partially cooled.

It was an heroic fight, with an heroic treatment, against a terribly fatal disease, but we won the battle.

I saw ten cases in all, after the two fatal cases, in my own practice and in consultation, the last case developing the following May. All the patients were bled, steamed, and treated with ice-water to the head; and all fully recovered with no sequelæ. The temperature, pulse, respiration, opisthotonos, eruption, some of which would and some would not disappear on pressure, and many other details were recorded, but the above facts are enough.

I am now asking myself in case I have the misfortune [illegible] the disease again, "Shall I trephine, aspirate the vertebral canal and use antitoxin, or shall I bleed?" I recognize that it will require much moral courage to resort to [illegible] section in the human subject in this twentieth century, but I incline to stand by my old friend, the thumb lancet, despite of my desire to keep abreast with the times, unless [illegible]

[illegible] belonging to the Stony Wold Sanatorium in the Adirondacks is recovering from cerebrospinal meningitis. During the attack the horse was bled freely. I mention this because it bears directly on what I have said, and is at least worthy of consideration.

F. W. Goodall, M.D.

MULTIPLE MYELOMA.

[illegible] there is an article by Dr. Joseph Collins entitled, "Multiple Myeloma (Kahler's Disease)." In it the writer describes the case of a man who during the last two years of his life suffered excruciating pain all over his body and became greatly emaciated. At the post mortem it was found that [illegible] containing round and spindle cells. Dr. H. Oertel, who performed the autopsy, is quoted as saying that he was willing to designate the tumor masses as myeloma because "this term has been used as one of situation rather than histogenesis." Dr. Harlow Brooks, to whom a series of sections were submitted, was "of the opinion that the growth was unquestionably a myeloma." The urine of that patient was examined at several periods during these two years and at no time a trace of Bence Jones' albumose could be detected. Dr. Collins states that cases of Kahler's disease on record number now about thirty-nine, and that his case is the tenth reported from this country. He sees the importance of this case in the fact that the urine contained no albumose and that, therefore, this case negatives the statement that the occurrence of albumose is pathognomonic for this disease. That last statement Dr. Collins quotes from my paper on "Myelopathic Albumosuria" (Medical Record, June 18, 1904.)

The difference between Dr. Collins and myself is, I believe, easily cleared up. I have described a case of myelopathic albumosuria. The thirty-nine cases of myelopathic albumosuria, or Kahler's disease, which are now on record and nine of which are reported from this country, all had Bence Jones' albumose in their urine. The presence of that albumose in the urine of such patients can, therefore, be considered as pathognomic for myelopathic albumosuria or Kahler's disease. The case of Dr. Collins', however, was not one of Kahler's disease, but was apparently a case of multiple myeloma of the type described by Buch, Runneberg, Hammer, Marckwald, Wieland, Abrikassoff, and many others. As far as I know, none of these cases is included in the list of Kahler's disease. It is true that as far as we know at present, all cases of Kahler's disease have their origin probably in multiple myeloma. But it is also pretty safely established that not all cases of multiple myeloma lead to albumosuria. Kahler's disease, or still better, myelopathic albumosuria, is a clinical entity; multiple myeloma, however, is an anatomical designation for post-mortem findings which might yet prove to be a group of heterogenous characters. The histogenesis of these tumors is certainly not yet a settled point; I need only to refer to the conflicting statements by Wright and MacCollum in this country. Dr. Collins' case in which all the bones were involved and in which none of them had shown any outward sign of the pathological condition present in the marrow differs also in that regard from most of the cases of myelopathic albumosuria, and resembles more some of the cases I have quoted above.

Finally I should add that my statement that "the occurrence of albumose in the urine is pathognomonic for this (Kahler's) disease" can logically be disproven not by cases of multiple myeloma without albumose in the urine, but by cases having albumose (in perceptible quantity) in their urine without the presence of myeloma in the bone marrow. Such cases have not yet been observed.

S. J. Meltzer, M.D.
107 West One Hundred and Twenty-second Street.

OUR LONDON LETTER.

(From Our Special Correspondent.)

COLLEGE OF SURGEONS—KING'S FUND AND THE SCHOOLS—PROPOSED UNION OF SOCIETIES—CONSTIPATION—PREVENTION OF [illegible] MINERS — HOSPITALS — LINCOLN EPIDEMIC—SHEFFIELD UNIVERSITY.

London, April, 14, 1905.

At yesterday's meeting of the Council of the Royal College of Surgeons a report was received from the committee appointed to consider the practicability of the college establishing a school for teaching the early and intermediate subjects of the curriculum. The committee estimated that even if successful the college would have to meet a yearly deficit of £3,400, therefore it would not be practicable to constitute such a school, as the college had no funds which could be applied for such a purpose. The council concurred in this conclusion. The Jacksonian prize was awarded to Mr. Herbert J. Paterson for his essay on "Such Affections of the Stomach as Are Amenable to Surgical Interference." The subject was selected for the Jacksonian prize competition for 1906. It is to be: "The Diagnosis and Treatment of Those Diseases and Morbid Growths of the Vertebral Column, Spinal Cord, and Canal Which Are Amenable to Surgical Operations."

The executive committee of the King's Hospital Fund has informed the twelve hospitals with schools that in accordance with the recommendation of Sir E. Fry's committee after January, 1906, grants will not be made to hospitals which contribute to the schools out of their general funds. Where hospital and school form a single institution separate accounts must be kept.

The meeting on Monday at the College of Physicians to consider the federation of the societies agreed that another attempt in this direction should be made, and a committee was appointed to prepare a scheme and report if possible in July. Naturally some differences were expressed, and the

difficulties may again prove insurmountable. The most formidable of all relates to property. The Medico-Chirurgical and the Medical, the two oldest societies, both hold property, and it is very likely that this fact may prevent amalgamation.

Mr. Arbuthnot Lane's proposal to treat chronic constipation by operation, as stated in my last letter, formed a stimulating opening, and a lengthy discussion on the subject followed, from which a few remarks may perhaps prove interesting. Dr. T. V. Dickinson, president, divided the causes into intrinsic and extrinsic. In the former group he placed muscular atony, glandular atony, hepatic inefficiency, chronic colitis, and mechanical causes, organic and functional. The latter group he summed up as hard water and improper diet. The several causes he discussed seriatim. Among the many points of treatment mentioned as appropriate to the various conditions, he remarked that castor oil was one of the best drugs, but should be given in very small doses—10 minims every four hours. This seems unnecessarily often, and patients who dislike the taste would probably rebel. But he had also given one drachm night and morning combined with belladonna; on which plan I would remark that the night dose only is generally sufficient. He also approved Kussmaul's method of injecting olive oil. Lack of sugar and lack of water in the dietary he thought played a part in producing constipation, and patients should be instructed accordingly.

Dr. W. H. Goddard had seen many operations, and held that Mr. Lane's methods were successful and his arguments logical. He had been experimenting in Paris on the colon of the dog and rabbit. The textbooks said one coat of the intestine contracted first, then the other, but he found both acted together. He rather minimized the functions of the large intestine. He believed in case of necessity a man could live without a colon. The loss of fat absorption talked of would not exceed 12 per cent of the amount digested, and the small intestine might very likely compensate for much of that, as it certainly would for water absorption. In chronic constipation the cecum acted as a cesspool, where injurious toxic substances were produced. Drugs might be useful before any structural alterations existed. After that the only useful measure was operation.

Dr. J. Foster Palmer welcomed a radical cure to partly restore the normal state and help some patients to begin a new intestinal life, and then was the time to impress on them the extreme importance of regular habits. But when no organic change had occurred he advised olive oil and warm water enemata and dieting. A sufficient amount of water should be drank. For neurotic, spastic cases bromides and antispasmodics were indicated; for stagnation from irritation or congestion belladonna, which relaxed the fibers and restored peristalsis; for atony or defective nerve power nux vomica.

Dr. Seymour Taylor added his voice to the importance of regularity of habit, and condemned the modern water-closet.

Dr. Collier, of Oxford, who has had twenty years' experience among rowing men, had not had one apply to him for chronic constipation—a fact he attributed to their exercises, which intermittently pressed the abdomen against the thigh muscles, forced bile into the bowels and further strengthened the abdominal muscles so they could treat constipation by voluntary exercises. Similar movements to rowing could be made. There was an enormous amount of humbug about massage. He took up a little book lately devoted to constipation, which attributed the prevalence of appendicitis to "unskilled" massage. Out of hundreds of cases he had seen none had been massaged at all. The abdomen would bear a good deal of rough knocking about and he believed in irritating it. In diet not enough fruit was eaten. Taking alcohol with meals led to lack of water being drank. Water should be boiled and drank freely. Sedentary habits, white bread, and tea all contributed to constipation. Olive oil was a good laxative and much used in foreign cookery. Enemata took up time and were discomforting. He had not met the changes described by Mr. Lane in the post-mortem room, but would look for them. The operative proposal would have an effect on physicians and general practitioners who could now lift the warning finger to patients who did not carry out their instructions, and tell them if they did not they would have to lose a good piece of intestine.

Dr. J. F. Smith, with long experience in the appearances of the bowels after death, had never seen those described by Mr. Lane. He admitted that constipation gave rise to symptoms so distressing that some would prefer operation, but they must not too highly advise it. The after history must be inquired into. Patients drifted into a condition demanding radical measures because they would not take trouble. Among simpler remedies he advised enemata of soap and water with olive oil daily.

Dr. Campbell Thomson dealt with the relation between paralytic affections of the intestine and the mechanism of secretion. As loss of power in a limb might come on rapidly or slowly, so might intestinal powerlessness. When of very long standing it might not be recoverable, and then the operation might be tried.

Dr. Leonard Williams said operation was not justifiable under 50 years of age. After that adhesions and vicious positions rendered restoration impossible, except by surgery. The factors were deficiency of fluid and inadequate peristalsis. These could and should be caused by the physician. Intermittent treatment always failed. The water must be supplied and the abdominal muscles kept in order by exercises. The point is to keep the bowel soft there and to aid the stimulus for the proper act. It must be right but continued. Belladonna and nux vomica were of value, and so was treatment with natural or artificial mineral waters. The effects of autotoxins in constipation were comparable to those of syphilis or alcohol. The treatment at spas was on the plan of small doses, largely diluted, and should be imitated in home treatment.

At the sixth annual meeting of the Association for Prevention of Consumption Lord Derby presided, and remarked that there had been disappointment in the results obtained in sanatoria, but he believed the check was temporary. The bad results were too often due to the admittance of hopeless cases for whom there should be special refuges. Sir W. Broadbent, who has pushed the movement from the first, moved a resolution that "it is necessary that consumption and tuberculous diseases generally should be dealt with in a comprehensive manner, and this would be done most efficiently by the Asylums Board constituting itself the sanatorium authority for London." Sir William declared well-to-do people ought not to have consumption, but it spread to them from the poor. Hopeless cases ought to be segregated and the Asylums Board could do for consumption what it does for fevers, "and it would not lead to much expense." Was ever so reckless an assertion made? Surely Sir William has heard of the extravagance of the Asylums Board; if not he should have consulted some less prosperous ratepayer before exposing his ignorance of its expenditure and the discontent of those who have to pay.

Dr. Treadwell gave evidence to the commission on the feeble-minded to the effect that at Parkhurst Prison a number of criminals not actually classed as weak-minded, owing to evil influences relapsed into crime. The prison rules were somewhat relaxed in favor of these convicts. The labor performed by them was gardening, road-scraping, cleaning, etc. Dr. J. H. Wilson gave his experience at Pentonville, and three other prisons. He was of opinion that the feeble-minded adult convict was generally an offshoot of the defective juvenile, and became in most cases the habitual criminal.

Princess Louise Augusta on Saturday opened new wards at the East London Hospital for Children. They have been built for the purpose of having a separate staff of nurses and accommodations for patients with whooping-cough, which is generally rife in the locality. The hospital is surrounded by poor mean streets overcrowded with inhabitants of the poorest class. The new wards are to cost £10,000, only half of which has been subscribed, but £3,000 has been promised on condition the remainder is raised before the end of June.

Guy's Hospital is appealing for £100,000 to pay for the new buildings, and for an additional £15,000 per annum to carry on the work. At a meeting of a special court of the governors last Friday Lord Rothschild in commending the cause to the public, remarked that Guy's Medical School is self-supporting, but he added that he was doubtful if the excitement about the schools could be justified in the interests of hospitals, and it should not be forgotten that men taught in them were better able to follow their profession to the benefit of the world.

A recrudescence of the epidemic of typhoid fever at Lincoln is causing renewed anxiety. There have been altogether nearly 1,000 cases and above 100 deaths.

Sheffield is to have the university it desires.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 27, 1905.

Chronic Bronchitis in the Adult as Influenced by a Change of Climate.—E. O. Otis calls attention to the fact that chronic bronchitis in the adult is often but one expression of degenerative changes in other organs, but it may require its own treatment owing to its persistence and the discomfort it entails. If it is allowed to go unchecked, it becomes more and more annoying with the onset of each winter season and easily leads to the development of emphysema, so that in addition to the paroxysms of coughing, dyspnea on any exertion and asthmatic attacks add to the patient's discomfort. The best plan of treatment is to send the patient to a proper climate, where he may live an out-door life, for the oxygen in the air is the natural disinfectant of the air tubes. In reply to the question,

What is the best climate for such cases? he says that in which the patient can pass most of his time out of doors, in a pure atmospere. A moderately warm, equable temperature, an abundance of sunshine, freedom from chilly winds and dust, are the essential climatic elements. The humidity is of secondary importance, although if the cough be irritative and the secretion scanty and tenacious, a rather moist atmosphere with warmth is desirable. He gives a chart showing the climatic characteristics of most of the well-known winter resorts.

New York Medical Journal, April 29, 1905.

Gallstone Disease; Remote Effects and Treatment.—S. P. Gerhard calls attention to the frequency of this class of maladies. It is often latent, but trouble is apt to begin as soon as the calculus gets out of the gall-bladder, unless it is so small as to give no inconvenience. If lodgment occurs in the cystic duct or neck of the bladder, we may have empyema or even gangrene of the viscus. If it stops in the common duct, near its orifice, the bile may be dammed back on the liver, causing cirrhosis, cholemia, and inflammation. Adhesions may result between neighboring viscera, causing vague gastrointestinal symptoms. Pressure on the head of the pancreas may cause inflammation of that organ (simple or hemorrhagic) and fat necrosis. In the bowel, the stone may irritate the wall and cause reflex contraction and ulceration. We know not how to prevent the formation of gall-stones. We may manage the diet, habits, and dress of our patients in the endeavor to prevent any interference with the bile flow. Deep breathing encourages the clearing out of the gall-bladder. There is no solvent which will disintegrate the stones when once found in the bladder. All patients subject to recurring biliary colic are advised by the author to submit to operation, but many refuse. Each case thus refusing must be carefully watched, and if a crisis arises, the case must be decided upon from its own conditions. Large quantities of alkaline waters are recommended. Excessive purgation is to be avoided. The catarrhal condition in the duodenum about the orifice of the common duct after a stone has passed out or after an operation can be very nicely overcome by the administration of tincture of colocynth in doses of ten to twenty drops three times daily before meals.

Primary Epithelioma of the Uvula.—Harmon Smith refers to previously reported cases and reports one personal experience in which occurrence took place after two operations for removal. His patient was a man of fifty-one years, who had been a heavy pipe smoker. The uvula was excised with a portion of the soft palate. Recurrence began about a month after operation, and a second intervention was made; this time the lower and right border of the palate as far as the right pharyngeal pillars being removed. Three months later a small, recurrent mass appeared in the upper angle of the wound, when a third operation was done. At the time of reporting the case, five months after the third operation, the patient was in good condition, with no evidences of recurrence. Full histological findings are given of the tissues removed. Smith finds that epithelioma of the uvula occurs at a comparatively early age.

American Medicine, April 29, 1905.

Adaptation and Tuberculosis.—J. G. Adami emphasizes the fact that in infectious diseases in general while the bacteria grow more particularly in one organ or tissue the successful counteraction of the disease is not a local matter. In fact, the tissues of the infected organ are so injured that they cannot themselves play any very active part. The counteraction is by the rest of the organism; in part by the leucocytes developed in the bone marrow and elsewhere, in part by other tissues, which discharge into the blood diffusible antitoxic and bactericidal substances. He calls attention particularly to the recent observations of Wright and Douglas that the phagocytic activity of the leucocytes is not called into play to any extent unless the blood serum contains certain substances which activate the leucocytes. These substances appear to be developed apart from the leucocytes, that is to say, by other tissues of the body. Applying these considerations to tuberculosis, he points out that when the tubercle bacilli grow locally there is a slow diffusion out of their toxins, and it is by the adaptation of the rest of the tissues to these toxins that the leucocytes and these other tissues become accustomed to produce diffusible antibacterial substances. In favorable cases these are present in amounts so considerable that the local growth of the tubercle bacilli is arrested and healing tends to ensue. Post-mortem observations show that this arrest is the rule rather than the exception. Applying these considerations to the treatment of tuberculosis, he shows first, that the tuberculin treatment is but an attempt to carry out the natural process; that turbculin is merely a concentrated extract of the toxins of the bacilli, and these now are injected into the organism at a distance from the site of local growth of the bacilli. Their action must be to stimulate the cells of the rest of the organism, and to produce increased amounts of antibacterial substances. The cells, however, may be in a state of low vitality so that they do not react, and hence this treatment is by no means constantly successful. Modern treatment similarly, he points out, is a carrying forward of the same idea. The disease as such is left severely alone, every attempt is made to improve the general tone of the organism by rest, good food, and fresh air. The cells gain improved tone and respond to the toxins, producing increased quantities of the antitoxic and antibacterial substances. Here, again, it is the body as a whole and not the local reaction that brings about arrest of the tuberculous process. The adaptive processes on the part of the bacilli are next considered. These also are capable of being modified according to alterations in their environments so that by passage they are found to adapt themselves more and more to the organism of any particular species. By passage through the organism of one species the bacilli become more and more virulent for that species and thus may become less and less adapted to growing the organism of another species. Dr. Adami is of the opinion that this is the case in general, and with tubercle bacilli grown in the human and bovine organisms respectively in particular.

A Case of Chorea, Apparently Fatal, from Excessive Muscular Action.—J. P. Crozer Griffith refers to the fact that death from chorea is unusual, the Collective Investigation Committee of the British Medical Association finding only 9 deaths in 439 reported cases, and Sinkler finding but 64 occurring in Philadelphia during 74 years. In the great majority of cases the fatal issue depends upon some complication, especially endocarditis, and deaths depending directly upon exhaustion from enormous muscular action must be considered a rarity. He repots an instance of this occurring in a boy of 11 under his care at the Children's Hospital of Philadelphia. The child had had a previous attack of chorea two years before. The cause of development of the present attack was not known. A month before, he commenced to show restlessness, which advanced to choreic movements and grimaces. For a week the movements had been excessive. On admission to the hospital nothing could be found abnormal in the organs, except the presence of a systolic murmur in the mitral area. The boy could not speak, although he seemed to understand perfectly. The movements were so excessive that the child was thrown violently about the bed, and was bruised all over. Sleep was almost absent. The condition was relieved to a certain extent by hyoscin hydrobromate hypodermically given, the administration of morphine, potassium bromide and chloral hydrate having been entirely ineffective. The excessive movements continued and exhaustion finally ensued, and death. The autopsy showed the presence of an endocarditis with microorganisms in the heart muscle and in the mitral leaflets. While it cannot be affirmed positively that death did not follow from endocarditis, yet the case bore all the evidences of death from exhaustion, the result of the enormous muscular activity.

Journal of the American Medical Association, April 29, 1905.

Autopsy Findings in Epilepsy.—B. Onuf reports the results of careful autopsies on sixteen epileptics at the New York State Institution for Epileptics. In twelve cases there were valvular changes of the heart, most frequently of the mitral valve (80 per cent.), less so of the aortic, and still less frequently of the tricuspid valves. These he considers generally as secondary results of the special strain due to the major epileptic attacks. Capillary changes, tortuosity, and aneurysmal dilatations were observed in several cases, and were attributed to the same causes. In eight of the cases where the lungs were examined there was acute pneumonia as a contributory cause of death. The cerebral changes were very striking. In ten cases there was a marked thickening of the pia, chiefly over the frontoparietal lobe. In other cases there were vascular lesions, circumscribed atrophy of one frontal lobe, subdural hemorrhage (one case), internal hydrocephalus (one case), cerebellar cyst (one case), and shrinkage of convolutions of vermis and adjoining cortex (three cases). The most striking changes, however, were noted in the thalamic region. These were in the nature of atrophy, sometimes the pulvinar, sometimes the other portions being most markedly affected. There was also an apparent discrepancy in the proportions of the geniculate bodies. Onuf discusses the possible relations of these thalamic changes to the epilepsy, but does not venture to express an opinion as to whether they are directly connected with the seizures or are only part of a general pathological condition of the brain. He suggests that there was probably an optic atrophy in some of these cases, and hence the importance of fundal examination in epileptics. The importance of good clinical histories in these cases is also emphasized.

Treatment of Gonorrheal Arthritis by Hyperemia.—Johannes von Tiling has secured excellent results from Bier's method of damming back the circulation with elastic bands in several painful cases of gonorrheal arthritis. He advises the use of a thin, pliant rubber bandage, applied so as not to cause discomfort, but sufficient to produce very perceptible hyperemia. Blueness and coldness of the limb, white or vermilion spots, and pain or paresthesia indicate that the bandage is too tight and should be loosened. Properly applied, the most marked first effect is relief of pain, but this is not all; damming, he claims, has a bactericidal effect, and dissolves away the adhesions, which are completely removed by massage after the removal of the bandage. At first the bandaging should be of short duration, a few hours at a time, but later it should be increased until it reaches ten hours a day and ten hours at night. After removal of the bandage massage lightly, then have the patient stand and move the joints. He claims that this method gives better results in most cases of gonorrheal arthritis tending to stiffness of the joints than any other.

Smokeless Powders.—C. F. Kieffer reports an investigation on the pathological effects of the fumes of the high explosives now so generally in use. A number of different powders were tested regarding the gases given out and the effects on the human system. The latter series was carried out in a room. Dr. Kieffer experimented on himself and on several members of the hospital corps by exploding a carefully measured quantity of the powder in a sealed room containing about twelve hundred feet of air space and observing the effects. The chief symptom was the well-known "dynamite headache," and the fumes seemed to have marked effects on the circulation and heart, with secondary effects on the nervous system. In some cases there was incoordination and diminution of hearing and of vision. Low tmperature seemed to aggravate the conditions, and at least one person was found who appeared to be immune. In most cases a certain amount of tolerance is gradually established. Kieffer also mentions a patient seen in Da Costa's clinic who could take six hundred and fifty drops of spiritus glonoini without serious effects. According to his findings, the gases to which the effects are attributable are carbonic oxid and nitrogen peroxid, especially the latter, though the symptoms are due to the combination of both. To meet the nitrite poisoning endeavor should be made to restore the vasomotor tonus, and strychnia is indicated in full doses. The carbonic oxid will be eliminated rapidly in moderate cases, but in severe intoxications oxygen inhalations and artificial respiration may be required. For the headache, coal-tar anodynes are not only useless, but dangerous. The best remedies are strong coffee and a linseed poultice to the nape, as advised by Key. The danger from these fumes is a real one, as numerous fatal cases testify.

Sterile Water Anesthesia.—F. W. Stevens has employed Dr. Samuel G. Gant's technic with sterile water for the production of local anesthesia in a number of operations for hemorrhoids, in other minor surgical procedures, and in one exploratory laparotomy, with the best results. In the latter case, as haste was required, the operation was finished under ether. By this method he anesthetizes the skin over the line of incision by repeated small injections followed by deeper ones for the underlying tissue. The advantages he claims for the method are rapidity of effective local anesthesia; absence of need of elaborate preparations; absence of toxic effects—nausea, vomiting, or straining; no fear from lung, kidney or heart complications; no after pain; and its value in emergencies in which other methods are not available. Operations for hemorrhoids can be performed in the office or at the patient's home, and need not cause loss of time or interruption of business. He recommends that the method be given a thorough trial, and thinks that when it has become more familiar its advantages will be apparent and its employment general.

Apparatus for Applying Hot Air to the Ear.—Albert C. Heath describes an electrical apparatus that can be used with any cautery battery for applying heat to the ear. He claims for it the advantage of proper graduation of the temperature by means of the rheostat; the possibility of definite [illegible] ployed; lack of danger of burning; simplicity of construction and management, etc. The air is heated by the cautery apparatus and forced through a rubber tube into the ear. By this means he claims the application of heat to the ear is made a definite therepeutic procedure, the amount being controlled and the application directly observed.

The Lancet, April 22, 1905.

Gallstones and Cancer.—G. R. Slade gives abstract histories of eight cases of carcinoma of the gall-bladder in association with calculi of that organ. His paper is illustrated by several photomicrographs. From a study of thirty other cases of calculi he found that sixteen contained stones while the bladder walls were smooth and healthy. In the other seventeen (ten being carcinomatous) there was evidence of chronic inflammation in the bladder walls, and in the majority of these cases the calculi were rough. The conclusions from the foregoing would seem to be that a smooth stone is not insufficeint to set up malignant change, and that we must have either a rough calculus causing persistent irritation or an infective cholecystitis with or without suppuration or possibly a combination of these conditions. As to the surgical significance of the above-named facts any preliminary investigation as to the existence of a "pre-cancerous" stage is manifestly impossible. The only fact is the presence of gall-stones, and in view of the very frequent association of gall-stones with carcinoma and of the impossibility of recognizing the early stages of carcinoma at the time of operation, the author thinks it would be sound practice, wherever it is surgically feasible and no obstruction of the common duct exists, to remove the gall-bladder in all cases where "chronic inflammatory thickening" is found in association with gall-stones. There is here no possible objection on the score of mutilation such as might deter one from making a simliar proposal with reference to the tongue and possibly also the female breast, and the gall-bladder, like the appendix cæci, though doubtless serving some useful purpose in the human organism, must still be considered, according to Slade, rather a luxury than a necessity of existence.

Three Cases Illustrating the Condition of the Small Intestine Some Years After Extensive Enterectomies.—A. E. J. Barker calls attention to the peculiarly distastrous effect of bowel paralysis in advanced intestinal obstruction. These show themselves to the operator in many ways, both before, during and after the relief of the obstruction. It has recently happened to the operator to observe the effect of the paresis on the living bowel some years after the relief of the obstruction, and several pertinent cases are reviewed. Three are reported, two of them being instances of hernia with gangrenous bowel, calling for exsection, are reported. In both the abdomen was opened after a long interval, once for another hernia and the other for some intestinal obstruction. In both it was possible to locate the sites of the anastomoses of the former operations. In both it was noted that while peristalsis on both sides of the anastromotic site was evident, the distal portion was far more active than the proximal, while the latter was considerably dilated over the normal lumen of the bowel. It was evident that the original paralysis above the obstruction had left behind it a certain want of tone in the muscular wall of the proximal portion, or blunted nervous irritability. Barker says that the paralysis is due in cases such as he narrates—not only to the exhaustion of the muscular coats from overstrain, but also results from the salination of all the layers of the bowel with toxins developed in the fermentary contents. This latter fact is evidenced from the common experience of finding the bowel edematous (in a case of bad obstruction) for several feet on the proximal side of the strangulation.

Plague in Cats.—A series of experiments performed by William Hunter leads him to offer the following conclusions: (1) Cats suffer from plague. (2) The disease may be acute or chronic. (3) The type of the disease is septicemic. (4) These animals may occasionally play a part in the dissemination of plague. (5) In plague-infected districts possible plague infection in cats is of great importance from a domestic point of view. (6) In plague-infected areas cats probably become infected through plague rats and mice which they devour as food.

British Medical Journal, April 22, 1905.

A Case Simulating Intracranial Tumor in Which Recovery Was Associated with Persistent Cerebrospinal Rhinorrhea.—T. R. Glynn and E. E. Glynn report this case. The patient, an electrical engineer, twenty-one years of age, had suffered from paroxysmal pain in the head and vomiting for a year. Both f[illegible] were excellent. In J[illegible] poisoning, due to the bursting of a pipe in a refrigerat[illegible] store. For a day or two he [illegible] the top of his head and remained at home for tw[illegible] When he tried to resume his duties, the headache and v[illegible] iting returned, and he had to give up work. For twelve months before his visit to the writer, in 1899, the headache generally occurred about ever fourteen days. At first it was limited to the forehead, but was later confined to the back of the head. It continued for three to four days and [illegible] The reflexes were disturbed, and there was marked optic neuritis. The next note, dated January, 1900, states that during the past twelve months he had been better and sometimes almost fit for work. Any attempt to stoop caused him to fall forward. During the next twelve months he became distinctly worse. His memory became very defective, and he grew lethargic and childish. He reeled

in walking and complained of a tendency to fall forward. His legs often suddenly failed, causing him to collapse to the ground. He continued to fail gradually, and on three occasions he suffered from epileptiform attacks, and he was nearly blind. He became apathetic and indifferent to his condition. Incontinence of urine finally set in. In June, 1903, clear fluid began to escape from the right nostril, coming in drops. Improvement began at once, and both mental vigor and muscular strength returned, and his sight was restored. In early August he was able to walk twenty miles. In October the patient stated that he felt perfectly well. His memory was as good as ever and he had returned to his work. Examination of the nasal cavity proved it to be normal. The escaping fluid presented the characteristics of cerebrospinal fluid. The discharge of fluid occurs only when the patient inclines his head slightly forward. It seems probable that adhesive inflammation occurred at the base of the brain adjacent either to the distended third ventricle or the distended descending cornua of a lateral ventricle, that a perforation occurred at this spot, and that the fluid found its way under considerable pressure to the perineural sheath of the right olfactory nerve. The prognosis in cerebrospinal rhinorrhea is unfavorable, as meningitis generally develops from the entrance of infective organisms into the cranial cavity. Any attempt to relieve the rhinorrhea by local treatment would be very dangerous for the patient, and it is not probable that any benefit would follow lumbar puncture.

An Inquiry Into the Existence of Typhoid Fever in Bermuda.—Lancelot Kilroy and F. W. Hooper here offer the results of an investigation carried out to determine whether cases of locally-acquired typhoid fever ever occur in Bermuda. The view is commonly held in the island that the disease does not exist there. A series of tests has been carried out in the naval laboratory at Bermuda. To ensure thorough control, three strains of undoubted Eberth and a pure culture of bacillus coli communis were put through the same tests side by side with three strains of organism obtained from the spleens of three fatal cases of this disease dying in the Royal Naval Hospital at Bermuda. The histories of all three cases show that the disease must have been contracted in Bermuda. Each strain of organism tested, except the colon bacillus, exhibited identical characteristics, and in no single test did the strains taken from these patients show any different reaction whatever to that shown by the strains of Eberth's bacilli which were used as controls. The writers feel justified in definitely stating that the strains in question were all three specimens of Eberth's bacillus. They were isolated from fatal cases of fever contracted in Bermuda, and had both the clinical and post-mortem macroscopical appearances of typhoid fever, from all of which it seems necessary to conclude that this disease exists in the island.

The Wider Use of Artificial Respiration in Therapeutics. Leonard J. Kidd believes that the scope of artificial respiration could be greatly enlarged. He thinks that it ought to be tried in rickets, malnutrition, habit-spasm, chronic Sydenham's chorea, immediately before epileptic attacks in cases showing an aura or any prodromata, in hysterical seizures, renal diseases, chronic constipation, asthma, many of the insanities, and so on. The method he would vary according to the case. And he would have it done many times a day. Both breathing exercises and artificial respiration could be used in many of the cases. It was found more than ten years ago that in hysterical attacks by holding out the tongue beyond the dental arch for several minutes, severe paroxysms which had resisted other treatment yielded to this method. In certain conditions caution would be desirable in using the method, as in myasthenia gravis and other bulbar affections. Even here the writer believes it could be used with some benefit. He concludes that the purest air should be used in these manipulations.

Oral Sepsis and Puerperal Septicemia.—Thos. Drake Leigh reports the case of a primipara who, ten days after a satisfactory labor, had a chill and a rise in temperature to 105 degrees. There was no abdominal tenderness nor offensive lochia. On the next day the patient spoke of trouble she had had with suppurating gums in connection with some decayed stumps. She had tried about three days before to open a small abscess in the gum with a safety-pin. The writer on examination found a small alveolar abscess which he opened, letting out a little pus. For several days the temperature was elevated. Two of the stumps were removed. On the thirteenth day of the illness the temperature fell to subnormal, remaining so for a week, when it became normal. Recovery was then uninterrupted. The septicemia had probably arisen from the predisposing sepsis of the gums, favored by the puerperal state, and as the writer adds, proximately from self-inoculation by the patient in her futile attempt to open the alveolar abscess.

Berliner klinische Wochenschrift, April 10, 1905.

Experimental Hydramnios in Nephritis.—Bibergeil says that Richter's researches have developed a method of producing experimental nephritis by means of injections of uranium nitrate together with the ingestion of large amounts of fluid by mouth. Wolf was able to produce artificial hydramnios by bilateral nephrectomy in pregnant rabbits, and the author endeavored to accomplish the same result by uranium injections. Two rabbits were treated in this way, and in each case it was found that not only were the usual transudates produced in the peritoneal and pleural cavities but that there was also a very marked increase in the amount of amniotic fluid. The fetal kidneys also showed nephritic changes, and in the one case there were pleural and peritoneal exudates in all of the eight fetuses and the urine in their bladders was albuminous. In each the freezing point of the amoniotic fluid was close to that of the exudates, and it contained glucose.

Mistakes in Hydrotherapy.—Winternitz says that a large part of the difficulty hydrotherapeutic procedures have had in winning general recognition of their value is due to improper methods of application. Success with these measures requires first, accurate analysis of the deviations from the normal of the organs or function in question, *i.e.* exact clinical knowledge; second, an understanding of the physiological action of thermic and mehanical stimuli; and third, familiarity with the technique of hydrotherapy. In febrile conditions the mistake is often made of employing baths at too low a temperature for a short time and frequently repeated, instead of longer and fewer but warmer ones accompanied by much friction. In cases of high body temperature with cold extremities and great vital depression with flickering pulse, subsultus, carphologia, etc., life may often be saved by cold packs to the trunk and the application of heat, friction with alcohol, etc., to the extremities. In the treatment of convalescent and chlorotic patients the mistake lies in the use of too high temperatures instead of making use of the stimulus of more energetic procedures. In sitz baths it is essential to protect the exposed portions of the body from cold, and much judgment is necessary if several forms of treatment are to be applied in a single case.

Münchener medizinische Wochenschrift, April 11, 1905.

The Etiology of Eclampsia.—W. Liepmann has made observations on rabbits which lead him to believe that the poison of eclampsia must be sought for in the placenta. He has already shown that it is possible to convert placental pulp into powder form without destroying its specific properties, so that salt solution extracts of this material may be used for injection into animals for purposes of immunization. In attempting to adapt rabbits to eclampsia placenta solution the experimental animals promptly died in from four to thirty hours, with all the evidences of severe intoxication, whereas animals similarly treated with the extract of normal placenta did not develop any symptoms. It was found possible to reduce the toxicity of this placental virus by keeping the solution on ice for four days, or by preparing it only at the moment of injection. Rabbits injected under these conditions remained alive. The author concludes from his observations that further researches into the nature of eclampsia should be directed to the placenta itself and that the specific poison may be isolated in this way, and perhaps an appropriate antitoxin be elaborated.

Experimental Observations on the Action of X-Rays on the Blood.—Helber and Linser exposed rabbits, rats and dogs to the *x*-rays for protracted periods of time, and found on making blood examinations that a very marked destruction of the leucocytes resulted. In some cases complete aleucocytosis was observed, but usually after the climax of leucolytic action had taken place a gradual, partial return of the white cells was noted. Histological study of the various leucocyte producing and other organs did not reveal any accumulation of the cells in these regions, so that it is evident that the process is a truly destructive one. The rays therefore appear to exert a selective action on the leucocytes, the nuclear substances being the most susceptible to the damage. The lymphocytes suffer earlier and to a greater degree than the other forms. The destructive process appears to go on not only in the blood forming organs but especially in the circulation itself. The red cells, the blood plates, and the hemoglobin also suffer to some extent but to a much less degree than the leucocytes. In nearly all cases renal lesions presenting the picture of an acute nephritis were observed, and the authors suggest that possibly a deficiency in alexin resulting from the wholesale removal of the leucocytes may have the effect of rendering the kidneys more susceptible to the action of bacteria.

Technique of the Gruber-Widal Reaction.—Schottelius recommends the following method of collecting blood to be used for the typhoid agglutination reaction. The great difficulty has been to induce physicians sending specimens for examination to secure a quantity large enough, so that on arrival in the laboratory it is possible to centrifuge off a sufficient amount of clear serum. The author's suggestion

is to make use of small sterile conical glass tubes, closed with either rubber or cork stoppers, into which a pin bearing a small pledget of gauze has been thrust, The stopper is sealed with paraffin. The puncture is made, preferably in the patient's ear, and the exuding blood soaked up with the gauze pledget. When saturated, the stopper with the pledget is returned to the tube and the broken paraffin seal restored by a moment's heating over the flame of a match. The specimen secured in this way is safe against drying out, and on reaching the laboratory it is easily possible to centrifuge the plasma out of the gauze. The same operation separates the clear serum from the corpuscles and accurate dilutions may then be made.

Deutsche medizinische Wochenschrift, April 6 and 13, 1905.

A Simple Means of Determining the Level of the Fetal Head in the Pelvis.—Thomass says that although the bimanual method has been found most useful in gynecological work, it is not used to the extent it should be in examining obstetrical cases. He recommends the following maneuvre for determining the position of the fetal head in relation to the pelvic brim. The most prominent portion of the head is located with the fingers in the vagina and the fingers of the other hand are then applied to the abdomen just above the symphisis, and pressed inward rather deeply. It is possible by the muscular sense to estimate very accurately the separation of the hands and therefore the degree of descent of the head, and the author gives details of measurement by which it is possible to determine the location of the parietal bosses, etc.

The Bactericidal Action of Light in the Finsen Treatment.—Klingmüller and Halberstaedter say that numerous experimenters have shown that the rays of the concentrated arc light exert a highly bactericidal effect when applied to bacteria in surface cultures on artificial media. The conditions are very different, however, in the treatment of lupus vulgaris, and the authors made numerous tests in different ways by means of which tubercle bacilli in the living tissues and in cultures were exposed to the Finsen rays. As the result of this work they came to the conclusion that in the Finsen treatment tubercle bacilli, even in relatively superficial situations, are not killed, and that the strongly bactericidal properties of light are not concerned in the treatment of cutaneous tuberculosis by this means.

Local Immunity of the Tissues and its Practical Significance.—Wassermann and Citron have shown that in addition to serum immunity there is another form which is extremely important and which they term local immunity. It is evident that some tissues are less vulnerable to bacteria than others; for example, the tissues of the mouth and rectum are much less susceptible to infection than those in other parts of the body. The colon bacillus is a harmless parasite as long as it remains in the intestine, but in the genitourinary tract it may give rise to severe infection. After an attack of typhoid fever the bacilli, which originally were pathogenic, may remain in the intestine for years without giving rise to any lesions. The virulence of the organism remains unimpaired, but the tissues have acquired an altered biological relationship to the bacteria, which is purely local, and, according to the authors, demands further investigation.

Clinical Observations on the Viscosity of the Blood in Disturbances of Carbon Dioxide Elimination.—Bence, by using the method of Hirsch and Beck, which renders it possible to determine the vicosity of the blood before coagulation and requires only very small amounts of material, comes to the following conclusions. The vicosity of the blood rises and falls in proportion to its carbon dioxide content. This interrelation depends on changes of volume in the red blood cells dependent on the presence of carbon dioxide, and may be demonstrated in the circulating blood. An excess of carbon dioxide in the blood overtaxes the heart, owing to the resulting increase in viscosity, and if it is due to cardiac insufficiency the circulatory activity is reduced. Oxygen inhalations reduce the viscosity of the blood overloaded with carbon dioxide, and therefore in some cases a weak heart may be relieved by this means. It was not found possible to modify the viscosty of the blood by any dietetic measures.

The American Journal of the Medical Sciences, April, 1905.

Myasthenia Gravis, with Special Reference to Ocular Symptoms.—Mortimer Frank declares that myasthenia gravis is rare, especially in children. Sex has a marked influence. The disease is most frequent in the female. It appears most often between the ages of twenty and thirty years. No real cause for this disease is known. Some prostrating infectious disease, such as tuberculosis or typhoid fever often precedes the affection. The onset is usually gradual. A most important symptom, and an early one, is ptosis. It comes on gradually and insidiously. As a rule, it is unilateral at the onset, but it soon becomes bilateral and more marked on one side than on the other. In the morning, after a night's sleep, it may not be present, but it rapidly becomes marked. It is always worse toward the end of the day, or after looking up for any length of time. The occipitofrontalis muscle is so weak that it offers no compensatory action. Complete and persistent ophthalmoplegia externa occurs without exception at some period of the disease. The intrinsic muscles are never paralyzed. Reaction of the pupils to light and accommodation always seem to be normal. Often there is inability to close the lids completely and firmly. Diplopia is often present; so is strabismus. The pathology is vague and uncertain. No evidence has been forthcoming that the disease is associated with any lesion of the nervous system. The prognosis seems practically hopeless, as regards recovery. The writer in speaking of the diagnosis states that it is easy in typical cases, when the rapid tiring and variation in the intensity of the symptoms with the myasthenic reaction appear; but the diagnosis is especially difficult, and at times impossible, in the early stages of slowly developing and atypical cases. The treatment consists first in absolute rest, gentle massage, and measures to keep up the nutrition. The writer reports a case of this nature. He believes that the most rational hypothesis is that the disease is purely a motor one, and that the lesion must be situated either in the muscles themselves or in the motor nuclei. The myasthenic reaction and the nature and distribution of the symptoms point to a disturbance in the muscles or the peripheral motor neurons, rather than to a lesion in the motor nuclei. Until something definite can be proved one can only theorize.

Myxedema Following Exophthalmic Goitre.—N. B. Foster reports this case, and says that these cases of myxedema following exophthalmic goitre are rare enough always to excite interest. This patient, a woman fifty-seven years old, declares that until 1887, she had always enjoyed good health. At this time she returned from South America and she noticed that her neck was considerably swollen. She was extremely "nervous," and her eyes were "swollen." She was told that she had a goitre. Over a year ago she noticed that her skin was very dry and came off in fine scales; her hair was dry and became very thin. She became "puffy" all over. Her memory became defective. She vomited several times a day clear mucus, which had an extremely offensive odor. On presenting herself to the writer for treatment, the thyroid gland could not be felt. The pulse was regular, 100 to the minute. The patient was put on thyroid extract, in addition to [illegible] treatment. Improvement was very slow, but after two months she left the hospital, far from well, however. It seems that she is now as well as she ever [illegible] is doomed to drag out a miserable existence. It is evident that there is another element in this type of myxedema besides deficiency of thyroid function, or else the administration of the gland extract would produce better results.

The Result of Splenic Removal.—James W. Hunter calls attention to the fact that in recent times we are beginning to realize that whatever the functions of the spleen may be, in many cases a splenectomy is not only justifiable, but eminently to be sought. It is not known if the spleen plays any rôle in the production of toxins or antitoxins. Patton, from his experiments on spleenless dogs, concludes that there is more rapid excretion of water after a meal, probably indicating a more rapid absorption, and that there is no essential change in the course or nature of the metabolism either during fasting or after feeding with the ordinary flesh proteids, with vegetables, or with food rich in nucleins. Certain experiments, also, are said to have demonstrated that the spleen is not the chief organ involved in uric acid production, even if it plays any part at all in the process. It is conclusively proved that the lymphatic glands take up the work of the spleen. They may or may not enlarge or undergo a change. In the writer's patient, a careful examination of the cervical glands, thyroids, and tonsils showed no abnormality. He cannot speak concerning compensatory changes in the mesenteric glands. Bayer states that the immediate results of splenectomy are an increase in the number of leucocytes, a decrease in the erythrocytes, and a reduction of the hemoglobin. The writer gives a report of his own case. It was a case of wandering spleen with a twisted pedicle. The spleen was removed, and weighed 700 grams. In it there were several old hemorrhages. The sloughing pulp was necrotic. The literature shows records of 22 operations on cases of wandering spleen since 1890. Of these in only 8 was there twisted pedicle. The writer's patient is now in excellent condition.

A Case of Universal Congenital Atrichia.—Augustus A. Eshner reports this case, which so far as could be learned is one of total absence of hair from all parts of the body, from birth. The nails also showed significant changes, and there was present also the rare anomaly of retinitis albicans. The patient was a house-painter, 64 years old.

The skin was soft, smooth, and unctuous. There was but little perspiration. The nails of the fingers and toes were only about one-half the normal length, and their distal extremities were irregular and longitudinally rugous. This appearance had been the same since birth. The condition here reported is exceedingly rare. The writer has found only a few similar cases in the literature to which he refers. Ziegler ascribes the failure of the hair to develop to local alterations in the external sheath of the hair root below the level of the excretory duct of the sebaceous gland. Pinkus uses the term hypotrichosis to designate the condition here reported. He believes the affection to be a developmental defect and not properly a disease.

Three Cases of Poisoning by Potassium Cyanide.—John Irvine McKelway describes these cases, saying that they are not frequent in this country. The first patient was a hair-dresser, and had stained her hands with a dye. A clerk gave her some pieces of potassium cyanide, to take off the stains, not telling her of the poisonous qualities of the drug. She went into the bathroom, which was small and imperfectly ventilated, where she rubbed the cyanide vigorously on her hands. In a few minutes, before she had an opportunity of washing her hands, she was attacked with vertigo and fell unconscious. She was carried into the fresh air, where she revived. Whiskey was administered. A little later she became much worse. Strychnine and atropine were then given, and improvement again took place. Recovery was uneventful. The other two patients took the drug internally, and both died. In the first case, poisoning took place by two methods—by inhalation in a close room and through the skin. The minimum lethal dose of potassium cyanide is generally fixed at from two to five grains. Recovery often takes place even after the ingestion of large doses. Unconsciousness generally persists from two to six or eight hours. The stomach is often found to be much inflamed, especially toward the pyloric end. Sometimes the lips, mouth, and stomach show evidences of corrosive poisoning. Promptness is the most important feature in the treatment of cases of cyanic poisoning. Probably the best drug as an addition to water in washing out the stomach is permanganate of potassium.

Eventration of the Diaphragm.—Joseph Sailer and Robert D. Rhein describe this condition as an abnormally high position of the left half of the diaphragm, with dislocation upward of the abdominal viscera, particularly the stomach, on the left side; hypoplasia of the left lung, and displacement of the heart to the right. It gives rise to physical signs closely resembling those of diaphragmatic hernia. The condition of this patient on his admission to the hospital is described as follows: The left side appears to be larger than the right; no cardiac impulse is visible on palpation to the left of the sternum. A distinct impulse is visible in the third, fourth, and fifth interspaces to the right of the sternum. The percussion note over the left side is tympanitic below and resonant above the second interspace. The tympanitic note extends from the midsternal line to the midaxillary line. There is a little fulness in the upper right part of the chest, and tenderness as far down as the second rib. The percussion note is resonant, but not tympanitic. There is an area of dullness continuous with the liver dullness, extending from the midsternal to the parasternal line in the third, fourth, and fifth interspaces. The respiratory sounds are absent on the left side below the level of the fourth rib anteriorly, and below the level of the third rib laterally. Below this point considerable gurgling and bubbling can generally be heard. Above the fourth rib the respiratory sounds are vesicular, but harsh. The heart sounds are faint on the left side and loud on the right side, and the second sound is distinctly accentuated. There is general cyanosis. The patient died in less than a month after admission to the hospital. The autopsy satisfactorily explained the physical signs. The writers report as complete a list of cases as they have been able to make. In making the differential diagnosis of this condition, all those conditions must be excluded that produce tympany in the lower part of the left chest. Among these, probably the most important is pneumothorax. The majority of analyses of the symptoms that have been published are based upon the study of single cases, and are, therefore, of suggestive value only.

French and Italian Journals.

Syphilis of Conception with Late Manifestations.—Léon Perrin calls attention to the method of infection of women by syphilis, called syphillis by conception. The father is syphilitic but gives no evidences of the disease. The mother becomes pregnant and is infected by a syphilitic infant. The disease is easy to demonstrate in the child. It often dies before birth, or is born before term, or if it is born alive it possesses the well-known stigmata. The evidences of the disease in the mother appear at very different periods. These syphilitic manifestations in the mother may occur soon after conception, or at the time of labor or much later. The early sign is the rash, which develops sometimes by the sixteenth day after conception. This is often followed by secondary manifestations of variable intensity, and these again by tertiary symptoms. However, the disease may remain latent during life or it may reveal itself through tertiary manifestations, even at the end of twenty years. Observations made in these cases prove that a woman cannot marry a syphilitic man with impunity. The dangers attending such a union are serious. Sometimes lesions which involve the skin, the eye, and the nervous system, occur at the same time. The writer cites an interesting case of a woman who married for her first husband a syphilitic man. After his death she married a perfectly healthy man, but the child she conceived by the second husband was syphilitic. It was cured by appropriate treatment. The mother had appeared to be in excellent health.—*Revue Française de Médecine et de Chirurgie,* April 17, 1905.

The Passage of Agglutinins and Antitoxins of Tuberculosis into Milk and Their Absorption by the Gastroenteric Tube.—F. Figari has made extensive researches on various animals as to the possibility of the passage of agglutinins and antitoxins into the milk, and their absorption by way of the stomach. He gives us his conclusions as follows: 1. Tuberculous agglutinins and antitoxins pass into the milk of cows and goats which have been immunized actively, and into the milk of rabbits immunized passively. 2. Kids born from immunized mothers inherit from the mothers defensive materials and increase them in amount as they nurse. 3. Calves and kids born of non-immunized mothers may absorb by way of the gastrointestinal canal agglutinins and antitoxins contained in the milk of immunized animals, and these agglutinins and antitoxins may cause the formation of new antitoxic and agglutinating materials. 4. Rabbits immunized passively, either subcutaneously or by way of the gastrointestinal canal, by administration of immunized milk, may transmit through the milk to their young which are nursing the antitoxins and agglutinins. 5. Adult rabbits nourished with milk of immunized cows absorb from the stomach the agglutinins and antitoxins contained in the milk, and in their serum are found other agglutinating and antitoxic principles.—*La Riforma Medica,* April 8, 1905.

Anuria Due to Calculi in One Kidney; Nephrotomy; Recovery.—Tuffier presents this report through Guibal. The patient, a man of 54 years, obese, had for several years suffered with crises of nephritic colic in the left side. In September of 1904 he had an attack of nephritic colic in the right side which was followed by absolute anuria. After eight days he consulted a physician for this condition. His general state was good, and only slight signs of uremia were present. He had two unusual symptoms, however, ascites, and a hydrothorax on the right side. On the ninth day after the beginning of the anuria, Guibal performed a right-sided nephrotomy. He found a kidney which was almost normal in size and appearance, with neither calculi nor urine in the pelvis or calices. He catheterized the kidney down into the bladder, but did not meet with any obstacle. Guibal concluded that he had to deal with a reflex anuria, believing that the other kidney, which for years had been the seat of severe paroxysms, was obliterated and atrophied. A drain was inserted through which a considerable quantity of urine escaped during the following days. At the end of seven days micturition had become normal and the drain was removed. Two months later the patient voided two small calculi. This case was then proved to be one of anuria by retention. The calculi which had been in the ureter had been pushed into the bladder at the time of catheterization. The ascites and hydrothorax were not explained.—*La Presse Médicale,* April 15, 1905.

Incontinence of Urine and of Feces in Late Hereditary Syphilis.—Marcel Cantonnet has collected in his thesis on this subject twenty-two cases, of which several are his own. He concludes that incontinence of urine is sometimes the symptom by which a meningomyelitis due to late hereditary syphilis reveals itself. It is sometimes associated with incontinence of feces. These two phenomena show themselves especially in degenerate subjects and in those with hereditary nervous taint. These phenomena occur at any age, but are most common between the ages of four and twenty. The lesions observed are those of meningomyelitis, which sometimes affects the lateral columns, at other times the posterior columns. There are two clinical forms: In one there is a diminution or abolition of the reflexes, corresponding with the latter condition; the other shows itself in contracture and exaggeration of the reflexes, corresponding to the first condition. Medullary symptoms are constantly associated with stigmata of hereditary syphilis. The prognosis should be guarded on account of the possible complications, both cerebral and meningeal. The sphincter disturbances are greatly improved by mercurial treatment.—*Revue Française de Médecine et de Chirurgie,* April 17, 1905.

Book Reviews.

THE INTERNATIONAL MEDICAL ANNUAL: A Year-Book of Treatment and Practitioner's Index. 1905. Twenty-third year. 644 pages. New York: E. B. Treat & Company, 1905.

THE present volume differs from its predecessors in being considerably larger, as would seem inevitable when we consider the remarkable activity in medical research which of late years has been steadily increasing. The work is fully up to date and gives concise articles on practically all subjects of recent change. Serumtherapy and organotherapy, radioactivity, all the latest drugs of value are well discussed. Surgical as well as medical subjects are both thoroughly treated, and even minor modifications are described. Not only is the subject matter of great interest, but its value is rendered doubly so by having the articles signed by an editor specially trained in each particular line. Quite a number of illustrations are added where they are required to make the text clearer, and bibliographical references at the end of various sections allow the reader to pursue his studies more extensively directly from the original sources. The volume concludes with a list of the principal medical works in the English language which have been published during 1904.

PRACTICAL PEDIATRICS. A Manual of the Medical and Surgical Diseases of Infancy and Childhood. By Dr. E. GRAETZER, Editor of the "Centralblatt fur Kinderheilkunde" and the "Excerpta Medica." Authorized translation, with numerous Additions and Notes by HERMAN B. SHEFFIELD, M.D., Instructor in Diseases of Children, and attending Pediatrist (O.P.D.) New York Post-Graduate Medical School and Hospital; Visiting Pediatrist to the Metropolitan Hospital and Dispensary, etc. Philadelphia: F. A. Davis Company, 1905.

THE chief charm of the work which is before us lies in its conciseness, its pithiness as it were. The author, who has been a pupil of Henoch, follows in great measure the teachings of his master, but at the same time writes of what he himself has seen and tried. Not only are the medical diseases considered, but also the surgical, the nose, throat, and ear, and the eye and skin disorders. The shorter second section gives chapters on hydrotherapy, electricity, massage, climatology, and dieting, and concludes with palatable prescribing, and a short materia medica, in which the children's doses are given. The American translator has done his work well, and has added some special articles on such subjects as intubation, bronchopneumonia, achondroplasia, home modification of milk, gonorrheal ophthalmia, antitoxin, etc. Perhaps the chief fault of the book lies in its paying so great attention to disease that it has not considered fully the hygiene and feeding of infants, but these subjects are so common in our American works that it would seem a wise sacrifice in a reference work of this size.

LEA'S SERIES OF MEDICAL EPITOMES. Edited by VICTOR C. PEDERSON, M.D. HOLLIS' EPITOME OF MEDICAL DIAGNOSIS. A Manual for Students and Physicians. By AUSTIN W. HOLLIS, M.D., Attending Physician to St. Luke's Hospital; to the New York Dispensary, etc. Illustrated with 13 engravings. Philadelphia and New York: Lea Brothers & Co., 1905.

IN this little volume the reader will find the diagnosis of the diseases and diseased conditions usually presented in books on Practice. So far as it goes this book can be commended; the signs, symptoms, and differential diagnosis are all that can be desired; and there is a large amount of useful information compressed into small space. But it does not go far enough. A book on Medical Diagnosis may fairly be expected to describe the various methods employed; in the present instance this has been done only in the case of the physical signs such as percussion, auscultation, etc. The methods of examination of the blood, gastric contents, urine, etc., are omitted; and to this extent we think that the title Medical Diagnosis (without limitation) is misleading, for these subjects are an essential part of medical diagnosis as understood to-day.

PROGRESSIVE MEDICINE; a Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; assisted by H. R. M. LANDIS, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. Philadelphia and New York: Lea Brothers & Company, March 1, 1905.

THE contributors to this, the first number of Progressive Medicine for the year, are C. H. Frazier, R. B. Preble, F. M. Crandall, C. P. Grayson, and R. L. Randolph. The subjects treated are the surgery of the head, neck, and thorax; infectious diseases, including acute rheumatism, croupous pneumonia, and influenza; the diseases of children; laryngology and rhinology; and otology. The ground represented by the above titles is well covered, and includes the recent advances made in the various subjects. This number is well up to the level of its predecessors, and is of considerable value, not only for reference but also as an evidence of medical and surgical progress. The various contributors have done much more than make a résumé of the literature of their subjects; they have infused somewhat of their own individuality, and the result is a production not only of scientific value, but one of considerable literary merit which it is a pleasure to read.

GYNECOLOGY, MEDICAL AND SURGICAL. Outlines for Students and Practitioners, by HENRY J. GARRIGUES, A.M., M.D., Gynecologist to St. Mark's Hospital in New York City; Consulting Obstetrical Surgeon to the New York Maternity Hospital; Consulting Physician to the New York Mother's Home and Maternity; Honorary Fellow of the American Gynecological Society; Honorary Fellow of the Obstetric Society of Edinburgh; Honorary Member of the College of Physicians of the German Dispensary; ex-President of the German Medical Society; Formerly Professor of Gynecology and Obstetrics in the School for Clinical Medicine, and Professor of Obstetrics in the Post-Graduate School and Hospital. With 343 illustrations. Philadelphia and London: J. B. Lippincott Company, 1905.

THE author of this book on Gynecology tells us that it was "particularly written for students in medical colleges and such general practitioners who desire to make themselves acquainted with the essentials of modern gynecology." This is a particularly modest estimate of what we consider a valuable book. The volume begins with chapters on Puberty and the Climacteric, General Etiology, Examination, and Treatment; Discharges from the Genitals. After this the diseased conditions of the vulva, perineum, vagina, uterus, tubes, ovaries, pelvis, urethra, bladder, ureters and rectum are discussed. There is also a chapter on Sterility. The book is throughout practical, and is written by a man who has had a wide experience not only in the practice of his specialty, but also in teaching and writing.

THE AMERICAN YEAR-BOOK OF MEDICINE AND SURGERY. Being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery, drawn from Journals, Monographs, and Text-Books of the leading American and Foreign Authors and Investigators. Collected and Arranged with Critical Editorial Comments, by SAMUEL W. ABBOTT, M.D., ARCHIBALD CHURCH, M.D., LOUIS A. DUHRING, M.D., D. L. EDSALL, M.D., J. CLAXTON GITTINGS, M.D., J. P. CROZER GRIFFITH, M.D., REID HUNT, M.D., WALTER JONES, Ph.D., A. O. J. KELLY, M.D., JOHN MARSHALL, M.D., Nat.Sc.D., J. H. W. RHEIN, M.D., DAVID RIESMAN, M.D., ALFRED STENGEL, M.D., A. A. STEVENS, M.D., G. N. STEWART, M.D., REYNOLD WEBB WILCOX, M.D. Under the General Editorial Charge of GEORGE M. GOULD, M.D. Volume I, Medicine. Volume II, Surgery. Philadelphia and London: W. B. Saunders & Company, 1905.

THE various annual summaries of medical progress have firmly established their value to all classes of professional readers, and the present year-books are among the most satisfactory of the number. The several departments are in the hands of men whose position insures good judgment in the selection of the material and skill in welding the separate parts into homogeneous and readable discussions. The general plan of arrangement and of typography, as well as the excellent indices combine to render the subject matter easily available for reference and therefore practically useful. In the volume devoted to medicine, the principal contributions of interest on the ordinary conditions are given due recognition, while we find that such recent subjects as trypanosomiasis, sleeping sickness, kala azar, dracontiasis, uncinariasis, in short, the whole tribe of the newer protozoal and intestinal diseases are discussed in the light of the most modern researches. New views on the nature of the infectious diseases, on hemolysis, antitoxins, etc., all receive adequate treatment. In the volume on surgery the advances made during the last twelve months in surgery proper, as well as in the allied provinces of obstetrics and anatomy, are treated with equal discretion. The section on the kidney and ureter, and on the prostate are especially noteworthy for the progress they record, and in the discussion of cysts and tumors some interesting papers on the nature of carcinoma are abstracted. Taken all in all there is much to be said in praise of the volume, and but little in criticism.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, April 10, 1905.

THE PRESIDENT, DR. THOMAS E. SATTERTHWAITE, IN THE CHAIR.

Symposium on Immunity and Infection.—Dr. EDWARD K. DUNHAM referred to the distinction that must be drawn between the acquired tolerance for poisons, as exemplified by the gradually diminishing susceptibility to drugs upon their prolonged use, and immunity. The toxins produced by bacteria and certain other poisons like abrin and ricin resembled food-stuffs in their chemical nature much more closely than did alkaloidal substances, and connected with that kind of constitution was their ability to call forth the production of antibodies, when introduced into man or animals. He referred to Ehrlich's theory of cell-receptors, and the part they were supposed to play in the physiological assimilation of food by the cell, in the susceptibility of cells to poisons resembling foods in their constitution, and to the production of antibodies. Of these antibodies, the physician was most interested in the antitoxins and bacteriolysins; but these classes of antibodies were only two of a large number of different kinds of antibodies. As

[illegible]

importance for diagnostic (Widal test for typhoid) or forensic purposes.

The antibodies might be divided into three groups according to the degree of complexity in their constitution, as inferred from their properties. Simplest of all were the antitoxins which possessed only a single combining affinity (the "haptophore group" of Ehrlich), enabling them to combine with and neutralize the toxin which had previously called them into being during the process of immunization. Next in complexity were the agglutinins and precipitins, which, in addition to the haptophore group, possessed a ferment forming a part of their constitution (the "zymophore group" of Ehrlich), to which they owed their characteristic agglutinating or precipitating property. Still more complex were the lysins, which possessed at least two haptophore groups of differing affinities. Where there were but two haptophore groups ("amboceptors"), one of these united with the food-stuff [illegible]xic substance (cytophilic haptophore group); the other with a ferment previously freed in the body fluid or cells. This second haptophore group was called the zymophilic haptophore, and the ferment with which it united was the "complement." "Polyceptors" were antibodies having several haptophore groups capable of uniting with more than one sort of complement.

Ehrlich had devised a nomenclature of which the fore-

[illegible]ressing the relations between the various kinds [illegible] stances involved in the complex phenomena of immunity. Dr. Dunham illustrated his remarks with a series of charts presented to him by Gereimrath Ehrlich, when he was in this country last spring, and pointed out the meaning of many of the terms used, as represented symbolically on these charts. In closing, he called attention to the nature of some of the difficulties encountered in the endeavor to obtain efficient antibodies for the prevention or cure of disease by means of sera.

Phagocytosis in Its Relation to Immunity.—Dr. EUGENE L. OPIE stated that the phenomena of immunity were now known to be so complex that there was little probability that they could be referred to the activity of any one organ or group of cells. Those who believed that the defensive substances of the body had their chief seat of activity in the body fluids, recognized fully that the constitution of the fluids was dependent upon the activities of cells, and the attempt was no longer made to separate, in a strict sense, humoral from cellular theories of immunity. It was, however, well known that certain observers maintained that processes upon which immunity depended occurred largely within one group of cells, and were brought about by substances intimately bound to the body of those cells. The observations of Metchnikoff had given importance to the fact that certain cells of the body were capable of engulfing and dissolving solid particles, and our knowledge of the character and behavior of those cells during infectious disease was largely due to the investigations of Metchnikoff and his pupils. A consideration of this subject was indeed in great part a review of the publications of Metchnikoff, who, with innumerable experiments, had attempted to answer the objections of the many observers who had opposed his theories.

According to Metchnikoff, the essential feature of an inflammation was phagocytosis. The vascular changes and other accessory phenomena which characterized inflammation were simply means by which cells capable of phagocytosis were brought into contact with the inflammatory irritant. The relation of phagocytosis to inflammation was well illustrated by the changes that followed the experimental introduction of bacteria into the peritoneal cavity of an animal. Many of the cells contained in the fluid normally present in the peritoneal cavity disappeared almost immediately after injection. At the end of about one hour, the polynuclear leucocytes accumulated in the blood-vessels of the mesentery and omentum, and hence migrated into the peritoneal cavity. These cells actively ingested the bacteria that had been injected, so that a few hours after the injection of an organism of only moderate virulence, the bacteria had completely disappeared from the peritoneal fluid. At the end of about sixteen hours after inoculation, a second type of cells made its appearance and gradually increased in number. This cell was larger than the polynuclear leucocyte, but was not unlike the latter in other characteristics. During the later stages of the inflammatory process, such cells engulfed and destroyed the smaller polynuclear leucocytes which themselves had already ingested bacteria, and when the exudate [illegible] undergoing resolution, many of the large cells were found containing half a dozen or more of the smaller forms. The large phagocytes Metchnikoff designated macrophages. The smaller polynuclear phagocytes, named by Metchnikoff microphages, were particularly concerned in the destruction of bacteria, but different substances influenced in varying degree the two types.

After reviewing at length the observations of Metchnikoff and others upon the rôle of phagocytosis in infectious diseases, Dr. Opie said that in recent years the theory of phagocytosis had doubtless had less influence in suggesting new and profitable directions of research than those which had been concerned with the properties of the blood serum and other fluids of the body. We were not yet able to define with complete exactness the part played by phagocytosis in the destruction of bacteria. Moreover, attempts to apply to therapeutic use the important facts that were known, had met with little success. Indirect stimulation of phagocytosis by the injection of substances which were capable of increasing the number of leucocytes in the circulating blood or at a point subject to bacterial invasion, had had little practical application, although attempts in that direction had been made. Albumoses, for example, injected intravenously or subcutaneously, caused at first a decrease of the leucocytes, and then a marked increase. As yet, however, no means of transferring these results to human infections had been devised. A somewhat more intimate knowledge was necessary before these facts of experimental biology were applicable to medical practice.

Therapeutic Value of Antitoxic Sera.—Dr. HARRY T. MARSHALL of Johns Hopkins University presented this paper. He stated that the antitoxic treatment of diphtheria was the best known and most successful example of serum treatment. The mathematical precision with which the serum acted when properly used; the importance of using

the antitoxin at the earliest possible moment after infection; the advantage of employing even extremely large doses of the serum, especially if its use was begun after the disease was well established; the greater rapidity with which immunization could be effected by intravenous injections, and the consequent advantages of that method over subcutaneous injection; the harmlessness of the serum; the local use of antitoxin as a spray, both to neutralize the unabsorbed toxin and as a means of hastening the disappearance of the diphtheria bacilli from the throats of convalescent patients; these were all matters that had been fully discussed in recent literature.

The diphtheria bacilli produced unstable poisonous bodies of complex but unknown chemical structure, called toxins. The toxins were readily soluble in the blood plasma, and were carried to the body cells for which they chanced to have a chemical affinity. The toxin united with the cell by means of the corresponding haptophorous or binding groups in the toxin and cell, and then, according to the virulence of the toxin and the vitality of the cell, either the cell was killed by the toxin or the cell reacted, throwing off the toxin and a number of haptophorous groups or free side chains or receptors, of the kind that had a chemical affinity for the toxin. These free receptors were the antitoxins; they would unite with any free toxins that might be present in the circulation, and even if the toxin was lightly bound to a cell, it might be dislodged if a great excess of antitoxin was brought to bear. Whether this phenomenon was due to dissociation was now a contested question, and was closely connected with the question of the complexity of the diphtheria virus. It was certain, however, that when once union between the toxin and cell was firmly established, no amount of antitoxin would influence the action of the toxin on the cell.

In tetanus, the conditions were different from those in diphtheria. The tetanus toxin was carried to the central nervous system along the motor nerves, and gained entrance to the nerve through the motor end plates. In their experiments, Meyer and Ransom demonstrated the presence of the tetanus toxin in the motor axis cylinders after a subcutaneous injection of the toxin, and they could prevent the toxin from reaching the cord by making an intraneural injection of antitoxin. After toxin was in a nerve, tetanic symptoms could be prevented by cutting the nerve or cutting the cord. The intraneural injection of toxin was followed by tetanus even though the blood contained a large amount of antitoxin. They found that the tetanus antitoxin was not carried along the nerves, and had practically no action excepting upon that toxin that had not yet entered into the motor axis cylinders.

There were two practical lessons of importance to be learned from the work of Meyer and Ransom. First, that subcutaneous, intravenous, and subdural injections of antitoxin were of no value as measures to relieve tetanus when the symptoms had appeared. Second, injections of antitoxin, especially near the infected wound, would effectually bind any toxin present in the tissue, *i.e.* before it had been picked up by the motor end plates. It was also probable that injections of antitoxin directly into the motor nerve leading from the infected wound, or even injections into the segment of the cord reached by this nerve would have some influence upon the toxins.

Therapeutic Value of Bactericidal Sera.—Dr. Herbert D. Pease, of the Antitoxin Laboratory of the New York State Department of Health, Albany, read a paper on this subject. He stated that, without question the largest volume of laboratory and clinical investigation looking towards the serum treatment of any of the infectious diseases, excepting diphtheria and tetanus, had been in the direction of a specific serum for the treatment of streptococcus infections. From the experimental aspect, the problems involved in the production of an effective antistreptococcic serum not only included practically all those concerned in the subject of immunity, but also those connected with the differentiation of bacterial species and races. With our very incomplete knowledge of the underlying principles of streptococcus infection, it was not surprising that the results obtained by the therapeutic use of the many variously produced antistreptococcic sera were also most uncertain and variable in the extreme, even after making due allowance for the personal equation in the reports of such results.

Owing to the lack of definite knowledge regarding the relationship of streptococci, there had existed two schools, one believing that all streptococci belonged to one species, and the other that streptococci could be divided into numerous groups, and that an immune serum, prepared by one strain had, at least, a greatly diminished antagonism to the others. The former group prepared sera with single cultures, the virulence of which had been artificially increased by their passage through animals—the so-called *Tier passage*—while the latter group prepared each serum with numerous cultures taken directly from man. Sera prepared according to both general methods had been used extensively clinically, and the reported results were numerous. In many of these cases infection by this microorganism was merely assumed.

With the serum therapy of tuberculosis, two names were most prominently associated, Marmorek and Maragliano. The former believed that tuberculin was not the true toxin of the tubercle bacillus. He claimed to produce the true toxin by growing certain tubercle bacilli in a glycerinated bouillon made from liver, to which was added the serum of a calf which had been subjected to injections of guinea-pig leucocytes. This so-called true toxin produced in the animals treated by it an antitoxic serum, which was used in the treatment of tuberculosis in man. From this serum, Marmorek claimed the most favorable results in acute miliary, in surgical, and even in the most severe cases of pulmonary tuberculosis. Maragliano's serum was prepared by the repeated injection of the filtrate of young cultures of tubercle bacilli, as well as the use of aqueous extracts of killed virulent cultures. He claimed that his serum was antitoxic and bactericidal as well. The most favorable results from the use of this serum in properly selected cases, were claimed by its originator. The classes of cases in which good results were not looked for by him, were those in which there was a mixed infection, or where there was a general impairment of nutrition. In opposition to the optimism of both Marmorek and Maragliano, Baldwin considered that the present sera used in the treatment of tuberculosis acted as non-specific stimuli, and merely assisted in the production of a high nutritional condition.

Dr. Pease said that notwithstanding our fairly satisfactory knowledge of the character of the infection in typhoid fever, and the demonstration of marked bactericidal properties in the serum of typhoid convalescents, as well as in typhoid immune sera of animals, there had been very few attempts to produce a therapeutic serum for this disease.

Before concluding his paper, Dr. Pease briefly discussed antidysenteric, antiplague, and antianthrax sera, and stated it was quite evident from his somewhat fragmentary review of the entire subject that in no one of the diseases considered had there been demonstrated an entirely satisfactory serum therapy. However, sufficient beneficial results had been obtained with some of the streptococcic, dysenteric, plague, and anthrax antisera at least to warrant some hope of better results when our knowledge of those infections and their etiological agents had become materially increased.

Diphtheria Antitoxin in Cerebrospinal Meningitis.—Dr. Arthur J. Wolff, of Hartford, Conn., read this paper, in which he said that early in the course of an epidemic of cerebrospinal meningitis which visited Hartford last year, it was observed that the characteristic organism found in the lumbar puncture fluid was not always decolorized by the Gram method, and it was also found that culture made from such fluid might be decolorized by Gram when the original fluids were not; in other words, according to the speak-

er's experience, the positive or negative reaction to Gram's stain was not absolute for the diagnosis of the meningococcus, and this agreed with the statements made by Jaeger, Pfaundler, and others. It would follow from these observations that the differential diagnosis of diplococci found in nasal or throat cultures, when based upon the Gram reaction, was as inaccurate as the attempt to differentiate by the same reaction the diplococci found in lumbar puncture fluid taken from actual cases of meningitis.

The rarity of diphtheria during an epidemic of cerebrospinal meningitis in Hartford in 1904, first led to an investigation as to the possibility of an antagonism between the two organisms. Various experiments were carried out, which tended to strengthen that belief. For example, cultures made in bouillon of loops from agar growths of meningococci from lumbar punctures, and loops from blood-serum growths of pure cultures of Klebs-Loeffler bacilli mixed, showed in some cases very rich growths of Klebs-Loeffler bacilli and very few meningococci, or *vice versa*, entirely dependent upon which organism was sewn in the greater amount. That such an antagonism might exist between these two microorganisms was entirely within the possibilities of bacteriological law, and similar examples might be mentioned almost without number.

The above facts, Dr. Wolff said, had led him to suggest the use of antidiphtheritic serum for the treatment of epidemic cerebrospinal meningitis, and if his suggestion would result in only a small diminution of the frightful mortality from a disease for which no remedy had hitherto been found, his object would be fully accomplished.

Limitations of Serum Therapy.—Dr. Henry W. Berg read this paper (see page 689).

Dr. William H. Park said that so far as he was aware, no great therapeutic advances had been made during the past five or six years in connection with antitoxic and bactericidal sera, nor was the future outlook very promising. Much had been learned about the nature of the various substances in the body that killed bacteria or destroyed their toxins, but many difficulties were encountered in the production of a bactericidal serum that would destroy the microorganisms that invaded the body. The speaker said he saw no pathological reason why diphtheria antitoxin should prove antagonistic to the organism of cerebrospinal meningitis. Probably three or four thousand dollars worth of antitoxin had been recently experimented with in that direction, and while, so far as he could see, it had done no harm, neither had it done any good.

Dr. James Ewing said that bactericidal sera destroyed bacteria, but left endotoxins that poisoned body cells and had a cumulative action, and against which there was no immunity. Moreover, the poisoned body cells discharged toxins and various poisons which had to be cared for by the organism, and hence bacteriolysis might be complete, but the patient die.

Dr. L. Emmett Holt said he had seen 49 cases of cerebrospinal meningitis during the past two seasons, the greater number of these being in the wards of the Babies' Hospital, and the majority of the patients being children under two years of age. The striking features of these cases were the irregularity of the temperature, the nervous manifestations, and the uncertainty of the prognosis, excepting in very young children. Of 21 under one year old, 16 died, while five were still under treatment, and would probably not survive. His experience had been that in children under one yar, the disease was fatal in practically one hundred per cent. of cases. Ten of the cases had been treated with antitoxin; eight in the hospital, two outside. The remedy was given in varying doses, ranging from six to forty thousand units. Dr. Holt said that he and his associates had been unable to see the slightest beneficial effect which could be fairly attributed to the use of the diphtheria antitoxin. It had apparently exerted no influence whatsoever upon the temperature, the nervous symptoms, nor the course of the disease. On the other hand, in no case did it appear to do harm. In the treatment of cerebrospinal meningitis, repeated lumbar puncture appeared to do more good than anything else. The withdrawal of a considerable amount of fluid—an ounce or more—from the spinal canal, was usually followed by a marked improvement in the character of the pulse, respiration, and the nervous symptoms. Many of these children, although hospital cases, were in excellent condition at the time of their admission, and furnished as good a test for the antitoxin remedy as private patients would have done.

Dr. Frank Grauer said that during the past five weeks he had employed diphtheria antitoxin in five cases of cerebrospinal meningitis, without any resulting benefit whatever. The patients were all seen early in the course of the disease, and the remedy was injected within twelve or twenty-four hours after the onset of the first symptom. Of two additional cases where the antitoxin was not used, one had recovered and the other was improving.

Dr. James C. Ayer said he had treated 48 cases of erysipelas with antistreptococcic serum. The result of the treatment in those cases was a diminution of the average duration of the disease as compared with those treated by the older methods. The duration of the disease under the serum treatment was about six and one-half days, while under the older method it was about nine and a half days. It also exerted a beneficial effect on the temperature, and rendered the patients much more comfortable. As a rule, they did not feel sick at all after the first injection of the serum.

Dr. E. Libman said he did not think Dr. Wolff had presented any proof that the diphtheria antitoxin and the meningococcus were antagonistic to one another. The mere fact that they did not grow well together in one tube did not prove it.

Dr. William H. Thomson said that in the course of his recent service at Roosevelt Hospital he treated 30 cases of cerebrospinal meningitis, none of them in children. Of the first 16 cases, 14 died; among the remaining 14, only two died. All of these patients received practically the same treatment, so the difference in the mortality could not be explained on that ground. Dr. Thomson said he had met with the same wide variation in the mortality rate in different series of cases treated during an outbreak of pneumonia, and he attributed it to a factor that had not been touched upon in the discussion, namely, that the greater mortality occurred in patients who were stricken during the height of an epidemic, while the reduced mortality occurred among those seen during its abatement. Until this factor of the stage in an epidemic of infectious disease was taken into account, the less said about therapeutic measures the better.

Dr. Wolff, in closing, said we had still much to learn about bacteria, toxins, and antitoxins. While the number of cases of cerebrospinal meningitis treated with the diphtheria antitoxin was still comparatively limited, it was growing daily, and definite conclusions could soon be based upon the value of that method. If it had effected even a slight decrease in the mortality of the disease, something certainly had been accomplished.

NEW YORK ACADEMY OF MEDICINE.

Section on Surgery.

Stated Meeting, Friday Evening, April 7.

Samuel Lloyd, M.D., in the Chair.

Results of Operation for Equinovarus and Other Deformities; with Plaster Cast Showing Original Condition of the Foot.—Dr. Robert H. M. Dawbarn presented this patient. The deformity was of the most pronounced type. The patient was a young man about 25 years of age, and he had never, until recently, been able to walk more than a very short distance because all the weight of his body fell entirely upon the outer side of the foot. Dr. Dawbarn excised the astragalus, removed the head of the first metatarsal, and performed tenotomy of the great toe tendon and of the tendo Achillis. The extremity was then put in normal posi-

tion and the skin wounds were closed. A plaster splint was applied and left on for six weeks, healing taking place under Schede's moist blood clot.

Result of Excision of Both Sternocleidomastoid Muscles.—Dr. Robert H. M. Dawbarn presented this patient. He said that for the past seven years the young woman had suffered from two distinct conditions, namely: (1) Greatly enlarged lymph nodules involving the entire left side of the neck, and (2) a pronounced lupus erythematosus. Fourteen months ago he operated through the customary cervical incision. Finding the exposure of the parts not sufficiently free he had divided the sternomastoid in its lower third. So great had been the tension of the subjacent hypertrophied glands upon the middle portion of the belly of the muscle that the circulation of the part had been profoundly interfered with. The result was that when it was cut below the middle third of the muscle it did not get sufficient nourishment, and together with a considerable segment of the vagus nerve had sloughed entirely away. That this complication ensued was attested to by the fact that the heart beats rose to 160 without corresponding temperature elevation. Furthermore, the patient's color was good and she was able to walk. The other vagus took on the function of both after several months. One month later, in order to avoid the development of torticolis, Dr. Dawbarn removed the muscle on the opposite side. Contrary to all expectations, there was no disability or the slightest sign of paresis as a result of this double removal of the sternomastoid muscles, for the girl was able to move her head forcefully in every direction. As the operator well said, this case, which was almost without parallel in medical history, proved that the sternomastoid muscles were far from being as necessary as usually supposed.

Dr. A. V. Moschcowitz said that he always preferred to remove the base of the first phalanx, it having been shown that the base of the first metatarsal entered largely into the support of the arch of the foot.

Dr. Willy Meyer also objected to the removal of the head of the first metatarsal, because flat foot might result.

Dr. Dawbarn gave the following reasons for the removal of the first metatarsal: (1) it, rather than the base of the phalanx, was the bone causing the deformity; (2) it had no muscular attachments; operation was most simple, whereas removal of base of phalanx must be done subperiosteally or else ruin the function of several muscles; (3) the assertion that the removal of the first metatarsal caused limping was untrue; at least this had been the operator's experience in upwards of 80 cases.

An Inflammatory Tumor.—Dr. Ramon Guiteras presented this case. The patient was 30 years of age. The lesion had been thought to be appendicitis, but operation had shown the mass to be extraperitoneal. It might have been a granuloma, but the diagnosis was doubtful.

Epithelioma of Lip.—Dr. Rowland Cox, Jr., presented this case. The patient was a man 64 years of age, who had presented himself for the treatment of an epithelioma, the removal of which necessitated the resection of one-third of the lower lip. Although there was no evidence of metastasis, the submaxillary glands were removed. A year later there was a recrudescence of the growth, but it was not a recurrence of the original tumor. It was probably an example of a secondary primary malignant growth occurring in a single individual, a condition occasionally reported, but one of exceeding rarity.

Salivary Calculus of Wharton's Duct.—Dr. Alfred S. Taylor presented this case. The lesion had occurred in a robust motorman, about 40 years of age. Its inception was marked by swelling and pain over the cheek whenever exposed to a draft. On inspection, the duct could be seen coursing along beneath the mucous membrane of the mouth for a distance of about an inch and from the stoma trickled a purulent thick saliva. A probe encountered obstruction 1½ inches from the stoma, but this did not feel as though it was due to stone. Immediately after the probing a great deal of yellow pus flowed out. As the probing was continued for some time a great deal of relief was experienced, and the gland which had been much enlarged, diminished in size. Finally a small calculus appeared at the stoma and was removed with forceps. The speaker said the stones of the parotid were only one-seventh as common as those of the submaxillary gland.

Appendicostomy.—Dr. James P. Tuttle read this paper. He said that although the operation had now been under trial for more than six years, only a comparatively small number of cases had been reported. He showed a most interesting series of patients, and cited twenty-two cases with one death due to acute miliary tuberculosis. Sixteen cases operated upon for amebic dysentery were all thoroughly cured or else well on the way to recovery. The patient's comfort and ability to carry out the treatment, which they in all cases soon learned to do themselves, depended, in the speaker's opinion, entirely upon following the technique, which he outlined as follows: If there was any contraindication to general anesthesia it might be done under local anesthesia, but the objection to this lay in the possibility of complications arising after the abdomen was opened There was little danger from the operation if proper antiseptic precautions were observed, as there was no necessity of opening the appendix until after the peritoneal cavity had been completely closed by adhesions. The leakage from the opening was exceedingly slight and barring the necessity of wearing a little piece of gauze over the aperture there were no disagreeable features connected with the treatment. The operation got rid of an organ which was always a menace to health and afforded ample opportunity for local medication of the diseased colon, and the patient was able to carry out the treatment for himself without pain or difficulty after the first week or ten days; it did not confine the patient to his room nor did it exclude him from society as did the artificial anus, and finally the opening could be easily and safely closed whenever the circumstances warranted it.

Appendicostomy and Cecostomy in the Treatment of Ulcerative Colitis.—Dr. Willy Meyer read this paper. He introduced the subject by exhibiting a number of patients who represented very clearly the technique used by the operator. After discussing the historical side of the operation at considerable length, he dwelt upon the advantages of appendicostomy as compared with cecostomy and concluded that the former was the operation of choice unless some peculiar variation in the situation or the morphology of the appendix contraindicated it. The technique which he had employed was characterized by two essential details. These were, that he made the appendicular incision a trifle lower than usual and brought out the appendix at the lower angle of the wound. Further, he advised and stated that he constantly practised the immediate removal of the appendix at the time of primary operation. He said there was no danger attached to this technique and if the parts were suitably protected with sterile pads, there could be no possibility of infection. The advantage of opening the appendix at the time of the operation was self-evident. In not a few cases the lumen was so stenosed as to be unavailable for the purposes of irrigation. This had better be found out at the time of operation when cecostomy might immediately be performed rather than later. In the latter event a secondary operation would needs be performed to the mortification of the operator and the discomfort of the patient.

Dr. Erdmann said that he considered cecostomy to be the better of the two operations.

Dr. Gant said that there were many cases of colitis which might be improved by irrigation. In his cases he had had one death two or three months after operation. In papillomata of the colon and sigmoid, appendicostomy was, in the speaker's opinion, an excellent method of preparing the parts for operation to be followed by excision of the tumor. Dr. Gant was very enthusiastic about the future of the operation and considered that as the profession be-

came better educated in regard to its possibilities it would be employed as frequently as the well-known operation of removal of the organ is to-day.

Dr. DAWBARN said that he had operated upon the second case ever done; he had used the following technique: The appendix was vigorously rubbed with dry gauze and brought out high up in the wound to avoid leakage. He did not believe in Dr. Meyer's method of carrying the appendix down to the lower part of the wound. He advised waiting 24 hours before opening the appendix in order that fibrinous exudate might form. Furthermore, he had not practised permanent catheterization of the appendix because he had not had any trouble in putting the catheter in at desired intervals. In regard to the type of irrigation, he said there was no reason why a continuous flow for 24 to 36 hours should not be maintained. He suggested also that as a matter of refined technique the mesentery of the appendix should not be cut because of the possibility of gangrene in the organ.

Dr. Tuttle, in closing, urged that the appendix should not be cut off until 48 hours had passed. This he considered only fair to the patients as in almost all the cases in which appendicostomy was indicated a delay of two days could work no possible harm. It avoided, he said, a small but pertinent risk, always attendant upon immediate opening.

Dr. Meyer said that one disadvantage of cecostomy lay in the fact that it necessitated the wearing of a tube. It was, therefore, safer and less disagreeable to the patient to utilize the technique of appendicostomy.

Dr. W. S. BRYANT presented an instrument for bone work called the "front-bent gouge." This was devised after the type of instrument used by wood carvers and its value lay in the fact that no mallet was required in its employment. The curve allowed of safe leverage to cut the bone free, and further there was no danger of slipping. It was, therefore, particularly accurate and one could always avoid accidental injury to the soft parts.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held April 17, 1905.

DR. FRANCIS J. QUINLAN IN THE CHAIR.

FOLLOWING the appointment by the President of three Inspectors of Election, and the declaration that the poll was open for the annual election of officers, reports of the various committees were presented.

Galvanism as a Curative Agent in Nervous Diseases; the Importance of Equipment and Technique.—Dr. W. B. PRITCHARD read this paper, in which he said that medical electricity was not as yet a science; we knew not what it was nor did we know its *modus operandi*, but only what it would do. The author's personal experience with galvanism alone constituted the subject matter of his paper. All neurologists accorded galvanism some degree of usefulness and gave it a legitimate position in the treatment of diseased conditions, although its field was a very limited one. He had never seen any real benefit in tabes dorsalis, although Erb had recommended it. In peripheral neuritis, or other peripheral nerve disease, and in many forms of neuroses, parasthesias, etc., galvanism occupied a place of great value. Also in the fatigue neuroses, in tired headaches of neurasthenics, especially the occipital and cervical forms, galvanism was of great benefit. He said there were no specifics in neurology, but that galvanism, properly administered, was of almost inestimable value. To get the best results one must have proper equipment and good tools. One should not guess at the dose of galvanism. A satisfactory outfit could be obtained at a nominal cost. He showed some electrodes made of pliable metal; instead of permanent covering he used clean towels. The electrodes were made as large as possible. Seances occupied from twenty minutes to an hour, the latter being the time employed in cases such as sciatica. It was necessary to have the electrode held firmly and in a comfortable position, in order to get the best results.

Dr. J. J. MCPHEE said that galvanism was an important aid in the treatment of anterior poliomyelitis. He had used it for eleven years in tabes dorsalis, but he had never seen any direct benefit from its use, although he believed that it might be of some value indirectly. He had never noted any good results whatever from the employment of galvanism in organic difficulties of the nervous system.

Dr. MILTON FRANKLIN said that the use of electricity for meidcal purposes was not a science and was far from being a science; but, if there was any one portion of electricity that had the rudiments of a science it was galvanic electricity. Its dosage could be absolutely measured. The static current was absolutely an unknown quantity in medicine. The *x*-ray influences upon tissues was known but had never been applied to neurotic conditions. Absolutely nothing was known of the high frequency current from a physiological or therapeutic standpoint, except that it had a superficial action on tissues such as would be caused by any cautery. But of all the medical electricities galvanism was the most important. The faradic current when compared to the galvanic was insignificant, or practically nil. Instead of clean towels to cover the electrodes he advised the use of lint which was cheap and could be thrown away after using. Long treatments were absolutely necessary in order to get the best results, and therefore, automatically held electrodes became indispensable. He had had good results in the use of the galvanic current in cases of anterior poliomyelitis.

Dr. WILLIAM M. LESZYNSKY said that the sensations of the patient should also be considered when applying galvanism. One of the most common accidents that occurred in this application was producing severe escars by burning, either from a leakage or some other defect in the equipment.

Dr. Pritchard closed the discussion by emphasizing the value of proper equipment and proper accessories. Nothing could do more harm in peripheral neuritis than a poor equipment; but with proper equipment and with the proper employment of the agent, nothing was of more value.

Clinical Features and Treatment of Epidemic Cerebrospinal Meningitis.—Dr. FRANCIS HUBER read this paper in which he reiterated many facts that had already been presented to various societies of late, especially regarding the clinical features. Because the germ was supposed to gain entrance to the meninges from the nasal cavities, the intranasal use of germicides should be of value. The boric acid spray into the nasal passages twice a day might be a method of prevention when placed in the hands of the public. This Jacobi had taught for some years. The mortality of cerebrospinal meningitis was from 65 to 70 per cent., and the main problem now confronting the profession seemed to be that of prevention rather than that of cure. It was to be hoped that the members of the Commission lately appointed would do much to limit the spread or outbreak of the disease. It should be remembered that the diplococcus causing cerebrospinal meningitis was possessed of feeble vitality, and that this organism could produce other affections and live in healthy mucous membranes. He referred to Jacobi's recent historical review of epidemics of this disease in the United States. In about one in ten cases one met with other cases occurring in the same house, or multiple instances in the same family, or transmissions to nurses or doctors, which made one believe it to be a communicable disease. On this account the friends of the victims should be cautioned against visiting the premises. It was a disease met with more in the crowded districts. During the past few months the disease seemed to be on the increase following a thaw. Nasal obstructions, as from nasal catarrhs, etc., seemed to render one more prone to the disease; this was noted in about one-fourth of the cases. One attack rendered immunity as a rule. During 1904 there were admitted to Gouverneur Hospital, 112 cases of cerebrospinal meningitis, 56 males and 56 females. There were 28 recoveries, or 25 per cent. Among those who recovered 14 were practically well in two weeks' time or less. In most of the

cases the diagnosis was confirmed by lumbar puncture and the obtaining of the meningococcus in the fluid. Dr. Huber showed charts of the milder cases, those that recovered in two weeks' time or less. Also he showed charts of the fulminant types, those that died within ten or fifteen hours, up to two, three or four days. The clinical features as seen in the cases of Gouverneur Hospital were detailed, following the classification as given by Osler. He said the intermittent type, which was denied by some authors, was frequently met with. Charts were shown representing the abortive type; these cases were practically well in ten days. He showed photographs of a child with chronic hydrocephalus; also one showing extreme bowing of the body. The number of deaths were 74; they occurred from fifteen hours of onset up to as late as 230 days. Fifty-six of the deaths occurred within 23 days; from the 29th day to the 230th day there were only 18 deaths; during the first 5 days there were 26 deaths; 57 per cent. died within the first 23 days. The cause of death in most of the cases was paralysis of the respiratory centers.

It did not seem to make much difference what form of treatment one resorted to, the results were approximately the same. Apparent convalescence was frequently interrupted by relapses. The patient should be isolated and carefully nursed in a well-ventilated room. The utmost importance should be given the general nutrition. Ice-bags might be applied to the head and support given the head and neck, which added greatly to the patient's comfort. Plenty of water should be used and the functions of the body well regulated. The urine should be drawn off if necessary. Often the use of nasal irrigations, because of the obstructions there, would be followed by some relief. The pain and restlessness could be controlled by morphine or codeine administered hypodermically. The headache could be relieved by one of the coal-tar analgesics without the aid of morphine. Ergot had been used, but without result. At times baths at 95° or 98°, with or without the addition of mustard, promoted sleep and quiet. He questioned the efficacy of the ice-bag to the head when the child was in the hot bath. Lumbar puncture relieved the intracranial pressure to a certain extent, besides being of diagnostic value. If the foramen of Magendie was closed, lumbar puncture removed fluid only from the subarachnoid spaces. In 51 cases in which one drachm of fluid was withdrawn, the diplococcus was found in 44 instances. At Roosevelt Hospital and Beth Israel Hospital, the intraspinal injection of diphtheria antitoxin gave quite encouraging results when first tried, but not later. In one case in which the injection was attempted, only a few drops of fluid could be withdrawn because of the gelatinous consistency of the exudate. The greatest hopes for the cure of the disease he believed rested in the application of proper hygienic measures.

Dr. Morris Manges said that nephritis was quite a common occurrence in this disease, and a large quantity of albumin was the rule rather than the exception. Unless one was careful when called to see a case of cerebrospinal meningitis he would mistake it for uremic coma, because of the albumin in the urine. Sugar was to be found in the urine in these cases very often, especially at the beginning; this probably occurred from local lesions in the brain. Ten years ago he had a sporadic case in which the presence of sugar in the urine was a puzzling feature of the disease. With regard to the rash, he said at the Mount Sinai Hospital the wonder was why this disease was called "spotted fever," for one of the characteristic features of the disease as seen to-day was the absence of any rash. Frequently herpes was noted and this lent aid to diagnosis, being one of the most important corroborative diagnostic features. Leucocytosis played an important rôle in diagnosis, sometimes the count running about 30,000 or 40,000. The variations in temperature constituted a striking feature of this disease, and an absence of fever was not any guarantee that the patient was free from the disease. At Mount Sinai there seemed to be a remarkable absence of serious complications. He never hesitated to use chloroform when doing lumbar puncture, and he had never seen any harm result. The importance of proper feeding was especially emphasized. He had seen good results follow the use of spinal injection of lysol, as previously reported by him. One case of streptococcus meningitis got well under its use, and this was the only case he ever saw in which recovery occurred.

Dr. Harlow Brooks said that we were not dealing with a toxic condition in cerebrospinal meningitis, as we were in diphtheria; the symptoms of this disease were not due to any toxin produced by the the organism, but were of mechanical causation. The clinical picture of the disease did not indicate any toxic condition, but pressure on cortex and ventricles. A toxin had never been isolated from any growth of the meningococcus. Therefore, it seemed to him that in such a disease in which the symptoms were the result of more or less pressure, but little help could be expected as the result of investigations such as now were being made by the Commission in the attempt to find an antitoxin. Epidemics of cerebrospinal meningitis had varied a great deal, and he himself had seen yearly variations. In 1896 and 1897 it was a true spotted fever; but this year he said he had seen only one or two cases in which these spots showed themselves. To-day herpes was more common. The organism varied remarkably in its ability to set up cerebrospinal meningitis; it was often present in the nasal mucous membrane and infection of the cerebral meninges took place, as a rule, through the nasal mucous membrane, but it was to him remarkable that, under ordinary circumstances, it was not able to set up disease process. Great difficulty was experienced in the identification of the organism, which could not be differentiated from the diplococcus catarrhalis or the pneumococcus except by cultural methods. The occurrence of metastatic foci was seldom seen; this organism did not set up metastatic process as other pathogenic organisms did. He said we were dealing with a strictly neurological disease. Too rapid removal of the fluid might have a fatal effect by too quickly relieving the pressure.

Dr. William M. Leszynsky said he had seen 35 cases of cerebrospinal meningitis at the Lebanon Hospital, with a mortality of 45 per cent. He had seen several fulminant cases, as well as cases that ran their course in a few weeks, and he had also seen the chronic cases. He had seen the disease occur among three children in one family. A mother and her infant had been brought to the hospital suffering from this disease at the same time. He saw one case of a boy, 15 years old, who had all the typical and characteristic symptoms of the disease and who made a good recovery, at the end of four or five weeks. The meningococcus had been demonstrated; yet he left the hospital perfectly well. At the end of five or six weeks, after employment as an errand boy, he returned to the hospital with a severe attack of cerebrospinal meningitis, and he went through another course of the disease and was again discharged a few days ago. The meningococcus was absent in the smear, yet present in the culture. Dr. Leszynsky had seen two cases of the abortive type, one occurring in a young girl of 16 or 17 who was menstruating; all the symptoms were very pronounced. She made a complete recovery and remained well without sequellæ. He had seen two other cases with well-marked nephritis which lasted about one week. He said that he had used ergot in place of morphine, chloral, or the bromides, for the relief of the pain. The use of ergot in cerebrospinal meningitis had now become the routine practice at the hospital. How it acted he did not know, but it was a clinical fact that it was of great value in relieving the pain and discomfort. In all the patients a lumbar puncture had been made, but he had never attempted to withdraw too large a quantity of fluid at the first puncture. He believed it was a cruel procedure to perform this operation without first administering chloroform, which was quite safe.

Dr. Alfred T. Livingston of Jamestown, N. Y., spoke of the effect of ergot on defective unstriped muscular fibers,

and said that it contracted abnormally dilated blood-vessels, having a favorable influence in inflammatory affections if employed sufficiently early.

Dr. Huber closed the discussion. He used ethyl chloride locally, when performing lumbar puncture which abrogated the pain, and he never used chloroform narcosis. The amount of albumin found in these cases was small except in the malignant types. A standing rule at the hospital was that the first puncture should be made for diagnostic purposes only, and only 10 or 15 c.c. should be removed; subsequently large quantities might be removed. He said he had used ergot by the mouth but, after hearing what he had regarding its effects, he would again try it subcutaneously.

Osteopathic Bill.—Dr. E. Eliot Harris said that this bill was in danger of passing within two days, and he asked all the members of the Association to write at once a personal letter to Senator Grady asking that he refuse to support it. Senator Grady's vote was necessary now to defeat this bill.

Election of Officers.—*President,* Dr. Francis J. Quinlan; *First Vice-President,* Dr. John A. Bodine; *Second Vice-President,* Dr. H. H. Seabrook; *Secretary,* Dr. W. R. Stone; *Corresponding Secretary,* Dr. C. G. Childs; *Treasurer,* Dr. Charles E. Denison; *Member of Executive Committee for Three Years,* Dr. H. A. Bodin; *Member of Nominating Committee 5th District Branch,* Dr. Wisner R. Townsend. Seventy-five fellows and alternates were also elected.

Philadelphia Neurological Society.

At a stated meeting, held March 28, Dr. Ralph Pemberton exhibited "A Case with Some Symptoms of Multiple Sclerosis Due to Trauma." The patient was a man about 22 years old, who, following a severe injury, presented tremor of the head and of the extremities, increased by voluntary movement, with some alteration in speech, but without noteworthy alteration in the reflexes, in the ocular movements or the eyegrounds. Dr. S. D. Ludlum exhibited "A Case of Alcoholic Multiple Neuritis, with Exaggeration of the Knee-Jerks." The patient was a man addicted to a steady indulgence in alcohol in moderate amounts, who complained of numbness, tingling, and pain in the lower extremities, with increase in the knee-jerks. The symptoms were attributed to a beginning multiple neuritis and the anomalous phenomenon was thought to be due to irritation of the nerve forming the motor segment of the reflex arc for the knee-jerks. Drs. J. T. Krall and T. H. Weisenburg exhibted "Cases of Injury to the Head, with Involvement of Some of the Cranial Nerves." The nerves affected were principally the optic, the third, the sixth, and the eighth, in varying combination, and the resulting symptoms comprised the optic atrophy, ptosis, internal strabismus, and facial palsy. Dr. Charles K. Mills exhibited a man who presented irregular incoördinate, involuntary movements in the right upper extremity, controllable by certain attitudes and diminishing in recumbency, and ceasing during sleep. The disorder was believed to be hysterical. Dr. Wm. Pickett exhibited a man presenting paralysis of the bladder, with retention of urine, for the relief of which suprapubic cystotomy had been performed. There was in addition abolition of the Achilles tendon jerks. It was thought possible the conditions were dependent upon incipient locomotor ataxia. Ralph Pemberton read a paper, entitled "The Direction of Turning in Organic Hemiplegia." It had been contended that in almost all cases of organic hemiplegia of organic origin the patient, in turning in the act of walking, moved toward the paralyzed side, while, on the other hand, in cases of paralysis of functional origin, the patient turned in the opposite direction, and this distinction had been considered of important diagnostic significance. Dr. Pemberton examined a considerable number of cases from this point of view and found that in about two-thirds the patients turned toward the paralyzed side and in the remainder to one or the other side indifferently. The direction of turning was governed by several influences, including the position of each foot in the act of turning, the presence of a possible means of support or of some obstruction on one or the other side, and probably, most important of all, the desire to make the paralyzed member stationary while rotation of the body is effected by means of the sound member. Dr. S. D. Ludlum read a paper, entitled "The Regeneration of Peripheral Nerves." He detailed experimental observations on lower animals, showing that regeneration took place only when the separated segments were united, and that there was no independent growth from the peripheral segment. Dr. Robert H. Chase read a paper, entitled "Insane Delusions." He called attention to the relation between the feelings of insane patients and the special character of their delusions. He pointed out the analogy between the false beliefs of sane persons and the delusions of the insane. Dr. C. L. Leonard read a paper, entitled "Treatment of Some Neuralgias by the Röntgen Rays." He repeated a series of cases of neuralgia of varied distribution, in a number of which great and permanent alleviation of the pain followed systematic employment of the *x*-ray.

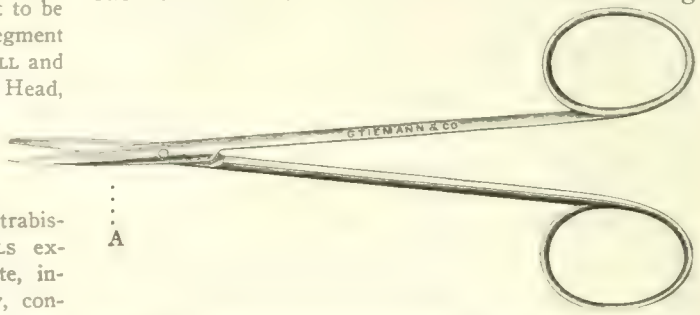
New Instruments.

SCISSORS FOR CUTTING SECONDARY MEMBRANOUS CATARACTS.

By EDWARD L. OATMAN, M.D.,
BROOKLYN, N. Y.
SURGEON TO THE MANHATTAN EYE, EAR AND THROAT HOSPITAL.

After the successful extraction of a cataract the vision may be obscured by the formation of a membrane in the pupillary area. If such a membrane is thin and confined to the capsule of the lens it may be opened with a knife and vision restored. If, however, the membrane has resulted from the organization of inflammatory products, it is usually thick and more or less adherent to the ciliary processes. These thickened membranes are very tough, and efforts to cut them with a knife may rupture the adhesions, lacerate the ciliary processes and produce disastrous inflammatory reaction.

The scissors here described are designed to cut such thick bands and membranes without exerting



Scissors for cutting secondary membranous cataracts. A, Knife edge ground on the back of lower blade.

undue traction on their attachments. The point of one blade is blunt, the other sharp. When held in position for operating the blunt-pointed blade is above, the sharp-pointed blade below. A keen *knife edge* is ground on the *back to the lower blade* for a distance of 4 mm. from its point.

The scissors are constructed with long blades for two reasons: first, ease of manipulation, and second, to avoid passing the joint into the anterior chamber.

To operate, the cornea is perforated with a keratome and the closed points passed into the anterior chamber. Now, when the blades are opened, the *lower,* with its sharp point and knife edge back, will easily perforate and pass below the membrane. The blades are now passed forward and the membrane severed. Two cuts in the membrane are better than

one, as it possesses a strong tendency to reunite unless the margins of the opening are widely separated.

When practicable, it is better to operate from above, as the patient's forehead affords support to the surgeon's hand. When operating from the temporal side an artificial support may be improvised if required.

The scissors are easily manipulated where iridectomy has been performed. If operating through a round pupil it should be dilated with both atropine and cocaine.

The blades are more delicate than represented in the illustration.

82 Remsen Street.

AN EMERGENCY POISONING CASE.

By JOHN W. WAINWRIGHT, M.D.,
New York.

It is a well-known fact that cases of acute poisoning more or less frequently occur when, if efficient means of treating such were at hand, lives might be saved and serious results averted. The medical practitioner, if called to a case of poisoning, nine times out of ten probably has not the proper remedies with him, and valuable time is lost in procuring the same. In some instances it means the difference between life and death. When acute poisoning is in question, prompt and energetic interference is indicated in order to safe the life of the patient. It would seem, then, that the necessary weapons for fighting the effects of poison should

form part of the armamentarium of every busy practising physician. I have recently devised an emergency case for this purpose, an illustration of which is here given.

The case is compact and handy, neatly finished in black leather, with a substantial handle. Its outside dimensions are 12 inches long, 4¼ inches wide, and 6 inches high. The contents are as follows: One stomach tube, one tongue forceps, one mouth gag, one 2-oz. glass syringe, one hypodermic syringe. It also contains large bottles of magnesium sulphate, of zinc sulphate in 20-grain powders, powdered mustard, calcined magnesia, and chloroform. The 1-oz. vials contain amyl nitrite, alcohol, iron dialyzed, acetic acid, oil of turpentine, and aromatic spirit of ammonia. The ½-oz. vials contain powdered ipecac, powdered opium, potassium bromide, chloral hydrate, potassium permanganate. The hypodermic tablets are of strychnine sulphate, morphine sulphate, pilocarpine, muriate, apomorphine hydrochlorate, nitroglycerin, digitalis, and atropine sulphate.

It is believed that this emergency poisoning case contains practically all the essential means for carrying on a successful fight against the effects of poison in the human system.

The case also contains a manual on acute poisoning, giving special symptoms, simple tests, chemical antidotes, physiological antagonists, and treatment.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Therapeutic Hints.

Conjunctivitis.—

℞ Zinci sulph. ..... gr. j
Morph. sulph. .....
Atropi. sulph. ..... āā gr. ss
Aquæ dest. ..... ℥j

Sig. A few drops in the eye two or three times a day.
—*Southern Practitioner.*

Sciatica.—Excellent results are reported from the daily injection of fifteen minims of the following solution into the painful region:

℞ Strych. nitratis. ..... gr. ii
Aq. dest. ..... ℥iii ss
Medical Press.

Helminthiasis.—

℞ Santonin ..... gm. 1.2
Glycerin ..... 14.
Syrup Sennæ. ..... 30.
Syrup Anisi. ..... 105.

Sig. One half to one teaspoonful as a vermifuge.
—*Osterr, Ztschr. f. Pharm.*

Diphtheria.—Williams speaks highly of the following when there is delay in obtaining antitoxin.

℞ Hydrarg. chlor. corros. ..... gr. i
Pot. iodid. ..... gr. xx
Glycerin ..... ℥ii
Aq. q. s. ad. ..... ℥viii

The dose for an adult is a tablespoonful, which may be frequently repeated if the case is carefully watched.
—*Clinical Journal.*

Tonsillitis.—If of rheumatic origin:

℞ Pot. Chlor. ..... gr. x
Tr. Aconiti. ..... ♏ v
Tr. guaiac Ammon. ..... ℥i
Mucilag. acaciæ. ..... ♏ xx
Aq. q. s. ad. ..... ℥i

Sig. Every four hours.—*Williams in Clinical Journal.*

Pernicious Malarial Fever.—Galloway uses for the cachexia of this disease a pill given after each meal containing:

Arsenous acid, grain 1-30.
Salicin, grains 3.
Reduced iron, grains 2.
Strychnin, grain 1-60.
Phosphorus, grain 1-200.
Podophyllin, grain 1-16.
Capsicum, grain 1-8.
Ext. Gentian, q. s.
—*New Orleans Medical and Surgical Journal.*

Seasickness.—Corning's prescription given every three or four hours is said to be an efficient prophylactic:

℞ Morphinæ, gr. 1/6.
Cannibis indicæ, gr. 1/4.
Nitroglycerin, gr. 1/300.
Strychnin, gr. 1/60.
Resorcin, gr. 1.
Cocain, gr. 1/6.

To make one pill or tablet. —*Medical Times.*

Prurigo.—

℈ Naphthol, 1.
solve in spirit. vini rect. q. s.
Vaselin, ad. 100.
—*Joseph in Archiv. f. Kinderheilk.*

Senile Gangrene.—The treatment varies according to the period of the disease. At the beginning, when the condition of the threatened region can be improved, recourse will be had to vaso-dilators or cardiac tonics, rest in bed with the limb bound in dry cotton wool to encourage the circulation in the affected parts, and as a therapeutic agent:

Iodide of potassium, 1 dr.;
Water, 10 oz.
A tablespoonful twice a day.

At the same time theobromine, an admirable diuretic eliminating the toxins of the blood, and a cardiac tonic, will be given in the daily dose of ten grains.

After twenty days of this treatment, trinitrin will be ordered for the last ten days of the month:

Solution of trinitrin 1-100, 40 min.;
Sulphate of spartein, 15 grs.;
Water, 12 oz.;
Three dessert-spoonfuls daily;
or
Nitrate of soda, 30 grs.;
Bicarb. of soda, 2½ drs.;
Nitrate of potash, 2½ drs.;
Water, 10 oz.;
Three dessert-spoonfuls daily.

Once the gangrene has set in, the above treatment can be continued, and local antiseptic treatment instituted. According to Dr. Huchard, lotions with permanganate of potash solutions (1-1,000) followed by the permanent application of compresses wet with oxygen water, recently prepared, is the best. —*Medical Press.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 29, 1905:

	Cases.	Deaths.
Measles	356	16
Diphtheria and Croup	294	42
Scarlet Fever	212	12
Smallpox	.....	.....
Chickenpox	61	.....
Tuberculosis	314	189

THE TUBERCULOSIS SITUATION IN PENAL INSTITUTIONS WITH ESPECIAL REFERENCE TO THE STATE PRISONS AT SING SING, N. Y., AND COLUMBUS, OHIO.

BY S. A. KNOPF, M.D.,
NEW YORK.

ASSOCIATE DIRECTOR OF THE CLINIC FOR PULMONARY DISEASES OF THE HEALTH DEPARTMENT; VISITING PHYSICIAN TO THE RIVERSIDE SANATORIUM FOR CONSUMPTIVES OF THE CITY OF NEW YORK; CONSULTING PHYSICIAN TO THE SANATORIA AT GABRIELS, N. Y., SCRANTON, PA., BINGHAMTON, N. Y.

LAST December, upon the invitation of the Prison Association, I visited the great prison of Sing Sing on the Hudson, in company with the Rev. Samuel J. Barrows, the Corresponding Secretary of the Association, Mr. Samuel McCauley Jackson and Mr. J. G. Phelps Stokes, members of the Executive Committee. I have been asked by them to write down my impressions of that visit and to make any suggestions which might lead to an amelioration of the tuberculosis situation, not only in Sing Sing, but also in many prisons throughout the United States, that are confronted more or less with the same problem.

This, for example, is true of the Ohio State prison, which I visited in March, 1905. Upon special invitation of Dr. Charles O. Probst, I inspected the State prison at Columbus, likewise with the view that my testimony might perhaps be helpful in bringing about the establishment of a new State prison, and the speedy carrying out of suggestions for an immediate amelioration of certain unsanitary conditions. The Prison Association wishes to incorporate such suggestions in its appeal to the Legislature.

Statistics are always of value and, as an introduction to my communication, I therefore reproduce the latest published statistics on tuberculosis in prisons that I could obtain. In a highly interesting and instructive article on "Tuberculosis and Cellular Confinement"* by Dr. O. J. Bennett, Prison Physician to the Western Pennsylvania Penitentiary, there appears the following "Statistical Table on Tuberculosis in United States and Canadian Prisons:

Prison.	States.	Years included in Table.	Total Deaths from All Causes.	Deaths from Tuberculosis.	Death Rate per 1,000 from Tuberculosis.
Auburn	New York	1891-1902	298	132	44.5
Sing Sing	New York	1891-1902	221	115	52
Columbus	Ohio	1893-1902	193	73	37.8
Jefferson City	Missouri	1892-1902	261	125	47.7
Joliet	Illinois	91-95-98-99	272	17	6.4
Richmond	Virginia	1891-1902	292	88	30
Eastern	Pennsylvania	1891-1902	167	105	62.8
Western	Pennsylvania	1891-1902	131	77	58.7
Wethersfield	Connecticut	1891-1902	128	48	38.9
Charlestown	Massachusetts	1891-1902	40	10	25
Moundsville	West Virginia	1891-1902	14	12	85.6
Lansing	Kansas	1891-1902	105	41	39
Fort Madison	Iowa	1891-1902	32	9	28
Central	Toronto, Canada.	1893-1902	22	1	5
State and county prisons	Alabama.	1893-1902	1399	592	42
Stillwater	Minnesota.	1891-1902	47	24	51†

The subject of tuberculosis in prisons is a vast one and it would require a deep sociological, statistical, and perhaps also geographical study to account for the frequency of this disease in some penal institutions and its relative rarety in others. An excellent report on this topic, prepared for the International Prison Commission and published as a Congressional document (House Doc. 142, 58th Congress), has recently been made by Dr. J. B. Ransom, the physician of the Clinton Prison at Dannemora. In the present short report of my visit to Sing Sing I shall only refer to issues which strike me as particularly important and deserving general consideration.

Before a prisoner is sent to Sing Sing, he has been detained for weeks, sometimes months, in city jails. As far as I can learn, prisoners who are simply held for trial or are waiting to be removed to Sing Sing, or any other State prison, are never examined by any physician unless they are ill and in actual need of medical attention. It must be evident that in this way a latent tuberculosis has a chance to develop, for even in the better city prisons the usual overcrowding will render the atmosphere vitiated, particularly in winter. If we add to this the lack of exercise and the depressing psychical influence of confinement, nostalgia and worry, we cannot wonder that prisoners arriving at Sing Sing are often found to be tuberculous, some even with very active lesions, while they may have entered the prison of detention seemingly in good health. Again, some may have been a little below par, underfed or weakened by exposure, and as a result have contracted tuberculosis from consumptive fellow prisoners while in jail.

It would thus seem that the first step toward the prevention of tuberculosis in penal institutions should be a most careful examination of all individuals and the weeding out and isolating of all tuberculous prisoners detained in jails. Only by a thorough physical examination, aided by bacteriology, and perhaps also by radiography, of every individual detained in jail, and the immediate isolation of true and suspected cases, will the authorities be able to prevent the infection of other prisoners and the unnecessary aggravation of the cases already existing. The tuberculous patient should remain isolated in the detention prison as well as in the penal institution, and he should be given the benefit of hygienic and dietetic treatment from the first moment he becomes a ward of the State or city.

When the time for his transfer comes, the history card of his disease and the recommendation of the physician should be transmitted with the other papers of the prisoner to the penal institution. After his arrival at the prison, in which he is to stay for some length of time, the physician will decide whether he is able to work or not, and what kind of work might be most conducive to his recovery. The occupations

* Bulletin of the Iowa State Institutions, October, 1904.

† The statistics of some prisons are misleading, as many prisoners are pardoned when it becomes evident that they will die from tuberculosis.

in Sing Sing, for example, are varied. Those which more or less involve the inhalation of dust will invariably render the tuberculous individual more ill, while they may not hurt the vigorous prisoner. The majority of the working rooms in Sing Sing are bright, well ventilated, and well kept. In some I thought the temperature too high. The installation of thermometers and the more frequent opening of windows, ordered by the guard on duty, would easily do away with overheating. The temperature in workshops should certainly never be higher than 65° F. in winter, and when the work requires much physical movement 60° to 62° suffices.

In the workshops of the Columbus prison there is a total absence of dust consumers. This absence of such an important sanitary device is explained by the sad fact that the contracts with the present men who control prison labor in Ohio, were made before is was possible to compel them to use dust consumers. In the cigar shops conditions are simply terrible. The shops are fearfully overcrowded. Tobacco workers under the best conditions, are prone to tuberculosis; how much more so must they be here where there is hardly elbow room, and the air is constantly vitiated. Since it is a very common practice for cigar-makers to paste the final leaf with saliva, it must be evident that no prisoner even slightly afflicted with tuberculosis should be permitted to make cigars, leaving aside the fact that such conditions are sure to aggravate his disease.

The old Ohio cell house, built in 1834, and the new one, built in 1861, are both antiquated in every respect. The cells at Columbus are not any better, and if anything, worse, as far as lack of light, air and ventilation is concerned, that at Sing Sing. As in the latter, the antiquated bucket system for the disposing of the excreta, adds to the terrible odor to which the badly housed prisoners and employees are constantly subjected.

Since it is, alas! too true that a goodly number of the young prisoners, who for their first offense are placed in reformatories, will relapse into a career of crime and often land in a penitentiary, I think it equally important that the young tuberculous offender, when arriving at the reformatory, should be given the same opportunity of recovering his health as the inmate of the prison. I am inclined to believe that the outdoor occupation, which should be given to this young offender, might even change his character for the better and diminish the tendency to crime which may have been fostered by unsanitary environment and lack of light and air in the overcrowded city tenements.

Leaving aside for a moment the sanitary construction of prisons, let us see what other measures can be taken to prevent the spread of tuberculosis in a prison. Not only should there be a careful examination of every prisoner for tuberculosis when he enters the prison of detention or the penal institution, but his chest should be reexamined periodically, at least once every three months. With this periodic examination a very incipient case, which might have escaped detection during the "entrance" examination is sure to be discovered before the disease has progressed to any considerable extent.

Expectorating, except in proper receptacles, placed for that purpose in cells, workshops, chapels, schools and on the grounds, should be punished by severe disciplinary measures. That there may never be an excuse for violating this rule, I would go further. I would not only provide a sufficient number of fixed, elevated, self-flushing cuspidors, such as, or similar to, the ones illustrated here (Figs. 1 and 2), but I would see that every prisoner has some sort of a pocket flask, made of metal, similar to those used in sanatoria for consumptives, of which I also give illustrations (Figs. 3, 4, 5, 6).

A prison is perhaps the only place in the world where spitting regulations can be rigorously enforced, and it is but fair that, if we say to an individual "don't spit here and don't spit there," that we should give him a chance to spit somewhere when he has an excess of saliva, a cold, etc. I am firmly convinced that with such a measure, not only would tuberculosis diminish in prisons, but epidemics of pneumonia and grippe would be less to be feared and more easily controlled. I should even like to recommend as a regulation that every prisoner must hold his hand before his mouth when coughing, whether this coughing spell is followed by expectorating or not. Thus, drop infection, that is to say, the expulsion of bacilli with droplets of saliva, will be avoided, and since the coccus of pneumonia is so very prevalent, even in the mouths of healthy individuals, this precaution may perhaps also tend to the diminution of pneumonia. As an additional measure to prevent drop infection, it might be well never to put

Fig. 1.—Self-Cleansing Elevated Spittoon with Supply Pipe.

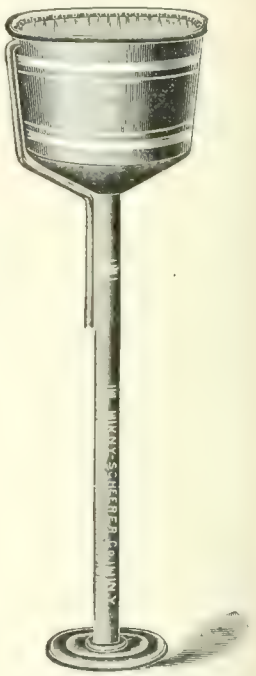

Fig. 2.—Elevated Self-Cleansing Street Spittoon.

prisoners too close together at the work tables. Whenever practicable, there should be a distance of at least three feet between them. It has been demonstrated that at that distance the droplets expelled during cough fall to the ground. It goes without saying that the personal and bed linen of the tuberculous prisoner as well as his clothing should be reguarly subjected to disinfection. The handkerchiefs of this class of prisoners should consist of squares of cheap muslin which should be burned after use.

To judge from the appearance of the various kinds of blankets, comforters, and quilts which were lying on the cots in the prisoners' cells, it seemed to me that these coverings might become the means of spreading infection, not only in tuberculosis, but in a good many other communicable and contagious diseases. The blankets and comforters are, as a rule, the private property of the prison inmate. He brings these articles with him, or they are given to him by visiting friends or by fellow prisoners who have been discharged. In most prisons these coverings, as well as the clothing which the prisoner wears on entering the penal institution are carefully disinfec-

ted. This precaution does not however, suffice to prevent the bed covering from becoming thoroughly infected afterwards, particularly with the germs of tuberculosis. Pulmonary tuberculosis is so insidious in the early stages, that the prisoner may have infected his bed clothing long before his disease has been discovered by the prison physician, unless, of course, frequent and thorough physical examinations of all prisoners are in vogue. To guard against infection which may arise from blankets, comforters, etc., having been soiled by tuberculous sputum or other infectious material, I would suggest that after thoroughly disinfecting these articles when they are brought to the prison, they be incased in a covering of light-colored washable material (not necessarily white), as one places a pillow in a pillowcase. By basting the blanket in its "blanket-case" it can be manipulated with as much ease as if not covered. With comforters and quilts the same method should be pursued. There should be two sets of cases so that the blankets need not remain uncovered while one case is being washed; thus the blankets never come in direct contact with the prisoner's body. I am convinced that with such a system and with the injunction that this washing must be done regularly, a factor of transmitting tuberculosis and other in-

Fig. 3.—Oval Metal Pocket Sputum Flask, manipulated with one hand.[1]

fections from prisoner to prisoner will be done away with.

Even the prisoner who is only suspected of tuberculosis should have his own cell, and, as far as possible, the placing of two prisoners in one cell should be avoided. The bucket system for receiving the dejecta of the prisoners during the night, and during the day when confined to their cells, is most deplorable. It is unsanitary in general, and as far as it permits the emanation of odors and gases, it is deleterious to the health of the inmate. The individual cell water closet, with a perfect trap and cover, such as are used in the better class of European prisons, is certainly to be recommended in place of the bucket system.

All prisoners should be given a chance to exercise several times during the day in the open air, even if it is only for a short time, and during that time they must not only be permitted, but should be enjoined, to take deep inhalations, or better yet, take regular respiratory exercises. The exercise in the open air should, however, not be limited to week days. According to the prison regulations now in vogue in most penal institutions, prisoners are confined to their cells not only from the hour of 5 in the afternoon, to 6 in the morning, but also during almost the entire twenty-four hours of Sundays and holidays, and when a holiday follows a Sunday, or vice versa, the prisoners are necessarily locked up in their cells for two successive days. That such close confinement in a small, ill-ventilated cell for twenty-four, and at times for forty-eight hours, must be harmful, is self-evident.

In all well-conducted prisons, prisoners are required to bathe regularly and their skin is usually in good condition. To the prisoner predisposed to tuberculosis, or one whose case is so incipient that constant medical supervision is not necessary, permission for daily cold douches should be given. To these classes of prisoners, predisposed or incipient, it seems to me also that it would pay the State to give food containing a little more of the nitrogenous substances and the carbohydrates than the regular prison fare now represents.

One predisposing factor to tuberculosis in prisons, which seems to have been overlooked in most of the reports on the subject, is overworking the prisoner. While it is true that in the majority of prisons the hours of work are rarely more than those of the average free laborer, we must not forget that the free man, laboring 8 to 10 hours a day, has a relatively better quality of food, the exhilarating influence of freedom of action, and naturally a superior hygiene. I do not wish to make this statement in the

Fig. 4.—Pocket Sputum Flask taken apart for cleaning.

spirit of criticism, but simply to point out the great likelihood of a predisposed individual developing tuberculosis more rapidly under such conditions than when in normal environments.

Wherever it is possible—and it would seem to me that it should be possible everywhere—the prisoners predisposed to tuberculosis and those in the earlier stages of the disease, should be assigned to agricultural work. The experience in Texas has shown that the inauguration of agricultural prison colonies is not only a benefit to the tuberculous prisoners, but also can become a benefit to the State financially. The history of the Texas tuberculosis agricultural colony, known as the Wynne State Farm, although dating back only a few years, is so interesting and instructive that I know it will be an inspiration to all interested in the tuberculosis problem to read a letter written some time ago by Dr. Fowler,* the distinguished prison physician, who inaugurated this system:

"After investigating the history of the institution, I found that about 50 per cent. of the deaths of both Texas prisons, at Huntsville and at Rusk, were due to tuberculosis, which seemed to be increasing every year, with no precautionary means toward stamping it out. The patients were all treated in the same ward, and under such

*Reprinted in the Bulletin of Iowa State Institutions, October, 1904, in the article of Dr. O. J. Bennett, above referred to.

circumstances I could see no chance for improvement I felt that something must be done to decrease this fatality. After giving the subject most careful consideration, I came to the conclusion that the best plan to pursue was to establish a tuberculosis farm, or colony, where the patients would have the advantage of outdoor life, fresh air and plenty of sunshine, and those not infected would be protected by the separation. I accordingly laid my plans before the prison officials, by whom I received a hearty endorsement and co-operation which brought about the establishment of the present Wynne State Farm in December, 1899. The location is a high, dry elevation, two miles from Huntsville, with no timbered lands near the prison buildings. This farm was formerly owned by the State and has been cultivated by convict labor for a number of years. The old prison building was converted into a hospital. I have everything on the place kept in a thoroughly sanitary condition The inmates are not allowed to expectorate on the floor or around the buildings. They are supplied with small wooden boxes filled with sawdust and calcium chloride to expectorate in, and these boxes are emptied every day and the contents burned. I also have the building disinfected. As to the kind of work the men do, it consists of light farming, gardening, poultry and stock raising. The garden products include vegetables of all kinds, and are used to supply the prisoners within the walls. All over this amount is placed on the market. The net proceeds of the farm for the past two years are as follows, viz., stock sold, $6,519.60; vegetables, $4,057.70. The men are all required to do some kind of work if they are able to be out of bed. I find the exercise is very beneficial to them in developing muscle and strength. It also causes deeper breathing, which helps to retain the normal elasticity of the lung tissue, and thereby supplies a greater quantity of oxygen to the system, increases the appetite and aids digestion. I believe, after watching results for three years, that a certain amount of physical exercise in the open air and sunshine is absolutely essential in the treatment of tuberculosis. I find that all the men who get out and take exercise improve with few exceptions, while those who remain in the building die without exception. In fact, there is more to be gained from the open air and sunshine treatment than from medicine, though I have them take the hypophosphites with cod liver oil and creosote, and treat symptoms, such as pain, cough, fever and night sweats when necessary. I insist on forced feeding, as it is beneficial in most cases, and I allow them to eat any wholesome diet."

The statistics of four years' working of this farm are as follows:

Total number treated		180	
" "	discharged		34
" "	pardoned		30
" "	transferred		37
" "	died		46
" "	on hand		33
		180	180

At the conclusion of Dr. Fowler's interesting letter he comments on the statistics as follows: "I will say that the thirty-seven men transferred are virtually cured, and at least one-half of those pardoned and discharged were in a good physicial condition, and the majority on hand are improving. The labor of the one hundred and eighty men was practically of no value anywhere else in the prison, as most of them had reached an advanced stage of tuberculosis before their reception at the Wynne Farm. The farm is more than self-sustaining, if the expense of guarding them is deducted. The men all occupy the same building, as they have to be guarded day and night."

From this report it is evident that tuberculosis has been on the decrease in that prison, and there is no doubt in my mind that the tuberculosis prisoner, cured through healthful, invigorating and natural agricultural pursuits, will, after the expiration of his sentence, be returned to society many times a better member of it than he was before.

The more advanced cases of tuberculosis, particularly those in which there is disintegration and correspondingly abundant expectoration of bacilli, should be treated in special wards and in summer perhaps in the special tents of the prison hospital.

In view of the character of the inmates of the hospital, I would insist, for the purpose of preventing drop infection, that all patients in the more advanced stage must wear a mouth mask. Patients in a number of European hospitals for consumptives are told to make use of such masks in order to protect themselves as well as the other patients. In a former article on "Tuberculosis in Prisons and Reformatories"* I gave an illustration of this instrument, which I reproduce here (Fig. 7). It is known as Professor Fränkel's mouth mask. I really think it is a valuable means to prevent drop infection which, with the advanced cases among consumptives, is quite a serious factor in the propagation of the disease.

By impregnating the gauze, which is held in place by the metallic frame of the mask, with some medicinal substance, the tuberculous prisoners could be made to believe that the instrument was worn for their own personal benefit instead of for the benefit and protection of others, or, as they might think, as a means of designating them as individuals suffering from a contagious disease. Thus, even the humane arguments for not using such a mask should have no foundation. Where these masks have been used, bacilli have been found almost constantly on the gauze. Fränkel's and Moszkowski's experiments have demonstrated the great value of these protective

Fig. 5.—Round-Shaped, Nickel-Plated Pocket Flask; manageable with one hand.

Fig. 6.—Cheap Metal Flask with Bayonet Closure.

masks, which can be easily disinfected. The gauze should, of course, be changed at least once a day and immediately be burned after removal.

Whether the practice of pardoning far-advanced tuberculous cases and restoring them to the homes of their often poor families is always a wise one I venture to question. It is often sad enough that persons who have contracted tuberculosis in prison, or whose tuberculosis has been aggravated through prison life, are discharged upon the community at the expiration of their sentences without any regard to where they will go or what they will do. They will invariably constitute a source of infection, unless they have been practically trained and are willing not to be such. Prisoners virtually dying from tuberculosis should not be pardoned and sent home, unless the authorities are sure that the unfortunate sufferer will not become a burden to his family, nor a source of infection.

A prison should be constructed so that there is plenty of light, air, and ventilation, on soil that is dry and porous. These conditions do not exist in our Sing Sing prison. The reason why there are not now so many tuberculous prisoners is that the watchful prison physician, Dr. Robert T. Irvine, sees to it that the majority of those discovered to be tu-

*Medical Record, March 2, 1901, and Report of the Prison Association of 1900.

berculous are transferred to Dannemora, which seems to be better fitted to cope with the problem. Since Warden Johnson had some large windows put in, the cell house is better lighted than in former years, but the structure in itself is, to my mind, thoroughly unhygienic. The soil on which the prison is built is constantly moist, and the stone walls retain the moisture to an alarming degree, so that the lower tier of the cell building is certainly thoroughly unfit for any human being to live in. The upper tiers are somewhat better, but they too are moist enough to foster tuberculosis as well as damp soil will do.

The degree of moisture on the walls of the cell house of the Sing Sing prison is really something hard to believe, unless seen with one's own eyes. I might be accused of exaggeration, and instead of giving my own observations, I will give those of Mr. J. G. Phelps Stokes, who is a trained medical man and well known for his philanthropic and social work, particularly in regard to prison reform movements. Here is his recent letter:

"184 Eldridge St., New York,
"February 6, 1905.

"My Dear Dr. Knopf:—

"In reply to your kind favor of the 30th ult., I am glad to testify as to the prevailing dampness in the cell building at Sing Sing prison. At times I have seen the moisture there so excessive as to be visible in myriads of drops covering large portions of the barred doors and the iron fittings of the cells. On one occasion I have seen such drops coalesce and run down the bars. Conditions have been mitigated considerably of late by the enlargement of some of the windows of the cell building, but I have recently been told by the Warden that even the extreme conditions above described are frequently observed still, notwithstanding the enlargement of the windows. The walls of the lower tier of cells are nearly always damp to the touch. The annual report of the Prison Association for 1900 contains much evidence bearing upon the defective sanitation of the prison.

"Very sincerely yours,
"J. G. Phelps Stokes."

The cells I examined at Sing Sing, while clean, whitewashed and well kept, had that characteristic odor of badly housed humanity. The architect who built Sing Sing hoped to avoid the effect of bad ventilation and overcrowding by placing a ventilation hole in each cell, but he did not take into consideration the class of occupants he had to deal with. I entered a number of these cells and found the ventilation holes stopped up with rags and clothing and over that a coat of whitewash.

Since dried whitewash, by its scaling process, will almost constantly produce a certain amount of dust in a small room like a cell, this becomes irritating to a sensitive lung, it is not unlikely that it may be an aggravating factor with prisoners who enter the penal institution only slightly tuberculous. Furthermore, a tuberculous prisoner may infect the walls of his cell either by directly expectorating thereon or by drop infection. The succeeding occupant, if at all debilitated, physically or mentally depressed, is strongly exposed to contracting tuberculosis in such environments, although the cell may have been whitewashed anew. The scales of the new coat of whitewash, gradually disintegrating into fine dust, uniting with the underlying tuberculous dust, make an infection by inhalation *par excellence*.

The method of inhaling tuberculous germs from infected walls has been demonstrated again and again, not only inside of prisons but in the tenement houses of the poor and even in the apartments of the rich.* Dr. Ransom, in his admirable report on "Tuberculosis in Penal Institutions," above referred to, expresses himself in regard to the delusion that whitewash is a cleaning and disinfecting agent, as follows: "Observation and experiment show that whitewash really promotes the spread of tuberculous disease, or it may do so. The fine scales and floating particles that emanate from the dry whitewash, when disturbed, not only irritate the bronchial mucous membranes, but they are also carriers of infection to the point irritated. This has been demonstrated to my entire satisfaction as the result of cell scraping." Dr. Ransom, in connection with this interesting observation, makes the following statement: "Certain experiments with lime burners also go to show that lime dust is favorable to the production of pulmonary tuberculosis."

To remedy the danger arising from whitewashing in small cells, I would suggest that the whitewash be replaced by oil paint which can be washed off with strong disinfecting fluids. The cells should, of course, never be smaller than 500 to 600 cubic feet, well ventilated, well lighted by natural light in daytime and by electric light at night (gas illumination absorbing too much oxygen).

In the Ohio State institution prisoners have the privilege to have their walls painted instead of whitewashed, if they wish to pay for it. The injustice of such a rule is evident. I am glad to report that upon my suggestion the painting of all the cells will be undertaken at the Columbus prison ere long.

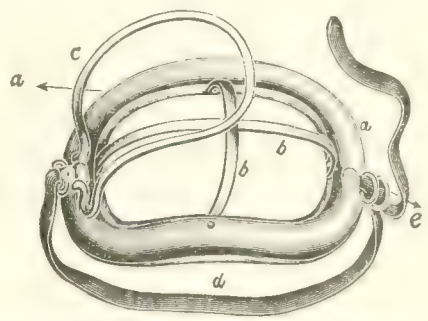

Fig. 7.—Frankel's Mouth Mask. (One-half natural size.) *a*, metal ring; *b*, supporter; *c*, saddle; *d*, elastic band; *e*, ring for fastening.

The perpetual moisture of the stone walls of the Sing Sing prison, which is greatly increased at high tide, adds in my opinion very considerably to the unsanitary condition of the cells and of this prison in general, and the sooner another locality is found with dry and porous soil, whereupon the State should erect a modern prison, where modern prison methods will be in vogue, the better will it be for the State and its people.

The most gloomy building at Sing Sing, by reason of lack of light, and perhaps also the most unsanitary, is the present "death house." It is the place where the prisoners condemned to death await their doom, but, owing to legal technicalities, they are often detained there for months and even years. The site for a new one has already been selected, and, I understand, work on it has commenced by this time. The new building will be larger and no doubt will have all the improvements in vogue in modern prisons.

At Columbus the worst portion of the prison is the portion assigned to the women, which is constantly overcrowded, and only a few cells receive direct light and air. Governor Herrick, most of the legislators, the medical profession, and the State Board of Health are strongly in favor of a new prison on a different site, and built with all modern sanitary improvements. In the meantime, according to reports received last week, a thorough cleaning has begun, and it is hoped that conditions will at

*Flick: "The Contagiousness of Phthisis," Philadelphia. 1888.

Biggs: "The Action of the Health Department in Relation to Tuberculosis," 1897.

Knopf: "Twentieth Century Practice of Medicine," Vol. X, p. 211.

least be made bearable until the new prison can be occupied. After the example of Sing Sing, larger windows will be made in the outer walls to admit the greatest amount of light and air in the cell houses, and the lower tiers will, if possible, be suppressed entirely.

That a careful prophyplaxis is well calculated to reduce the mortality from tuberculosis in penal institutions has been demonstrated by carefully gathered statistics from the prisons in Prussia. Before the era of prevention, (1875 to 1878), there was a mortality from tuberculosis in these prisons of 118.0 per 10,000, while with the inauguration of preventive measures (1892 to 1894), the mortality rate was reduced to 81.0 per 100,000. (Cornet, "Tuberkulose," Wien, 1899.)

It is our right and duty for the good of society to confine the criminal and punish him, according to the gravity of his offense, by years of seclusion. But, however great the crime he has committed may be, we have no right to sentence him to contract tuberculosis. But, leaving aside all altruistic considerations, for reasons of protection and self-preservation, it is our imperative duty to do everything in our power to isolate all tuberculous prisoners, to treat every prison inmate afflicted with tuberculosis, and to give each one all the best possible chance of cure. By adhering to this policy there will be fewer tuberculous prisoners discharged upon the community and consequently a diminution of centers of infection.

During my visit to Sing Sing I had occasion to appreciate the courtesy and helpfulness of Warden Johnson, and noted with pleasure the kindness and consideration he manifested toward his unfortunate wards. What he needs, to my mind, to still improve the efficacy of the institution, besides the sanitary improvements suggested, is more helpers, better helpers, and better paid helpers. If I were a New York statesman, I would think it wise to spend just enough money to render the cell building at Sing Sing temporarily sanitary; I should insist upon the filling up of the lower tier of cells with some concrete substance, and build, in addition, a system of drainage whereby the rest of the building might be kept at least relatively dry.

The legislature should, as soon as possible, appropriate enough money to build a model prison on a suitable site. The State of New York should not be behind in prison reform, and this new prison should do away with the old system of high walls and dark cell punishment, and resort to the more modern and humane method, paying less attention to the construction of walls and punitive measures and more to reformational methods, such as are exemplified by the institution at Mansfield, Ohio. By the system of gradation, which awards the prisoner for good conduct, not only by diminution of time of imprisonment, but also by increased comfort and consideration for his personal wellbeing, there are observed less infractions against prison rules, less tuberculosis and less disease in general, fewer attempts to escape, fewer repeaters in crime, and more reformation. It would seem that the modern and more humane method of treating the prisoner in our penal institution more as a fellow-being morally diseased to whom the most humane methods should be applied, is, after all, the most profitable one, not only to the individual, but also to society at large.

Comparative Longevity.—In a paper read last month before the German Congress for Internal Medicine, Dr. B. Laquer contended that life in America is in general shorter than in Germany, and this in spite of the fact that Americans are more temperate in the use of alcohol and work an average of 10 per cent. shorter hours.

DERMATITIS SEBORRHOICA AND ITS RELATIONS TO ALOPECIA AND OTHER CONDITIONS.*

By L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

It is now nearly twenty years since Unna[1] of Hamburg first directed attention to what he denominated *Seborrheal Eczema,* now better known as Dermatitis Seborrhoica, or Eczema Seborrhoicum. The subject immediately attracted the attention of dermatologists, and a large amount of literature has appeared concerning its features and nature. It has been thought desirable to offer the present writer's clinical experience with the disease, to examine some of the relations which may exist between it and certain other conditions of the skin, notably Alopecia, and to study its true character.

Unna rightly recognized that many quite different eruptions were grouped under the general name of chronic eczema, and called attention to certain of the dry, scaly forms in which there was a more or less preponderance of fatty matter, including many cases formerly called pityriasis capitis, some previously recognized as psoriasis, etc. Since that time pretty clear descriptions of various skin conditions belonging to the process have been given, and dermatitis seborrhoica is now quite generally recognized as an entity.

It is unnecessary to enter here into any prolonged description of this eruption, of which some account will be given later. Suffice to say that it is accepted as a definite cutaneous affection, with more or less accurately determined features, but all the phases claimed by Unna and some others have not received universal acceptance.

Dermatitis seborrhoica may be defined as a chronic, more or less inflammatory affection of the skin, probably of microbic origin, exhibiting varying degrees of scaliness, generally of a greasy character, on normally colored or moderately congested skin, with a tendency to extend (generally from the head downwards) by sharply defined, commonly circular areas. It is frequently accompanied with itching, which, however, is not as severe as in eczema. Most observers agree that the eruption is primarily one of the scalp, causing one of the forms of dandruff, where it may remain confined for years, and suddenly develop elsewhere, as a scaly eruption, or with more or less inflammatory symptoms.

My experience with dermatitis seborrhoica alone, in private practice, relates to 777 cases recorded as such, among 7,997 miscellaneous cases of skin diseases, seen since the eruption was recognized. It thus formed 9.7 per cent. of all. During the same period there were seen 1,913 cases of eczema, or 24 per cent., and 346 cases of psoriasis, or 4.32 per cent.

In addition to this, among 596 cases recorded as alopecia (excluding alopecia areata) there were 273 cases in which dermatitis seborrhoica played a prominent part, making a total of 1,050 cases exhibiting the disease under consideration, or something over 13 per cent. of the whole number of skin cases seen.

A large number of such cases were also treated in my clinic at the New York Skin and Cancer Hospital, but the exact number seen by me were not separated in the general statistics. During the last seven years, in which dermatitis seborrhoica has figured in the published reports, there were 1,370 cases of the disease treated at the hospital, among

*Read before the Medical Society of the State of New York, January 31, 1905.

23,712 miscellaneous skin cases, or 5.8 per cent. of the whole. Psoriasis formed but 3.6 per cent., and eczema about 26 per cent.

The ages of my patients with dermatitis seborrhoica are recorded in the following table:

TABLE I. DERMATITIS SEBORRHOICA.

Ages.	Males.	Females.	Total.
0-10	16	18	34
10-20	35	75	110
20-30	90	114	204
30-40	124	83	207
40-50	75	48	123
50-60	41	19	60
60-+	22	17	39
Totals	403	374	777

From this table we find that dermatitis seborrhoica affects both sexes in about equal proportions—403 males, 374 females. While the disease was observed at all ages from one year to eighty-nine years of age, it is mainly an eruption of middle life, and between the ages of twenty and forty there were 411 cases, or almost 53 per cent. of the whole.

Among these cases of dermatitis seborrhoica we find, on examining the notes, that alopecia was a prominent feature in 284 patients, which, added to the 596 recorded as alopecia (excluding alopecia areata), gives a total of 880 cases, whose ages are shown in the following table:

TABLE II. ALOPECIA.

Ages.	Males.	Females.	Total.
0-10	1	5	6
10-20	27	64	91
20-30	165	174	339
30-40	107	158	265
40-50	40	81	121
50-60	13	26	39
60-+	1	15	16
Unrecorded	1	2	3
Totals	355	525	880

Examining now the relations between dermatitis seborrhoica and alopecia, we find, as above stated, that of the 777 cases so recorded, 284 patients, or 36.5 per cent., presented a great loss of hair. This occurred about the same in both sexes, though rather more frequently in females—37.4 per cent. to 35.7 per cent. in males.

Turning to the alopecia cases, we find that of the 596 recorded under this diagnosis, 273 cases, or almost 46 per cent., were due to dermatitis seborrhoica. These, added to the 284 previously mentioned, make 557 out of the 880 cases of alopecia in the table, or over 63 per cent., nearly two-thirds of the cases, in which loss of hair was due to dermatitis seborrhoica.

Croker[2] gives 466 cases of what he terms seborrhoic alopecia among 5,083 miscellaneous skin cases, or 9 per cent. of all. Elliot[3] found dermatitis seborrhoica in 316 out of 344 cases of premature baldness. It may be stated that the majority of dermatologists now accept the view that this disorder, still called by some seborrhea, the eczema seborrhoicum of Unna, or dermatitis seborrhoica, is the most fruitful cause of loss of hair, although all are not agreed in regard to the basic cause of the disease in question.

Sabouraud[4] has made very elaborate studies upon what he terms seborrhoic maladies, which cover practically the same ground as Unna's seborrhoic eczema, and differs from him materially in his explanation of the method by which the destruction of the growth of the hair takes place. Both of them, however, and other observers, are agreed that the disturbance in the epidermis and sebaceous glands is due to a microbe or microbes which as yet have not been absolutely identified. This is not surprising, considering the large number and variety of microorganisms which have been found on the scalp and body; different investigators have claimed various cocci and bacilli as the active agent, and no real agreement has yet been reached.

Enough has been learned, however, to establish pretty clearly that dermatitis seborrhoica in all its forms is more or less contagious, and that very much of modern baldness is caused thereby, and therefore is of parasitic origin. Its development is, however, undoubtedly favored by the various elements which lower the vitality and render the skin more susceptible to operation of such local agencies.

Some of the most interesting and important points in connection with dermatitis seborrhoica are its simulation of a number of other well recognized cutaneous affections; to read the descriptions which have been written by various observers it would be difficult to readily recognize the disease in all its aspects, and to differentiate it from some other eruptions which it more or less resembles, on various parts of the body.

One of the most puzzling phases of the eruption is that in which it simulates *psoriasis;* and yet it is particularly important to know and recognize this form of it, because of the very different prognosis and treatment of the two affections. Many a rebellious case which had been previously diagnosed as psoriasis has yielded quickly to suitable treatment for dermatitis seborrhoica.

It would be impossible to detail fully here all the elements of resemblance and difference, but a few illustrative points may be given. The differentiation demonstrates forcibly the necessity of examining the whole of an eruption and recording the history of a case, before an accurate diagnosis can be reached. It continually happens that the circular, circinnate, or gyrate lesions, reddened and scaly, on one portion will at once suggest psoriasis, when a careful study will show that the real nature of the eruption is quite different from what was anticipated, and the scalp may be found to exhibit characteristic dermatitis seborrhoica. Or, again, certain lesions in the axillæ or groins will suggest the true nature of the eruption, and a more careful examination of the patches originally seen will then demonstrate features, in the shape, scaling, etc., different from psoriasis. The history of the case, showing long existing scaling of the scalp, and the development of the eruption from above downwards, etc., will also often help materially in the diagnosis.

Dermatitis seborrhoica may likewise simulate *tinea* or *ringworm,* both on the scalp and on the free surfaces of the body; but here the microscope will aid in determining the true nature of the eruption. The same is true of *tinea versicolor,* but the tawny brownish color of the latter and the absence of all congestive redness should prevent error.

Pityriasis rosea may also be simulated by the eruption under consideration; but the very superficial character, and the slight scaling of the rosy-colored eruptnon should distinguish it.

Some of the eruptions of *syphilis* may also be imitated by dermatitis seborrhoica, but a full knowledge of the case, together with other lesions in the mouth and throat, etc., and a very careful study of the eruption should suffice to differentiate between the two.

Not only does dermatitis seborrhoica simulate many other eruptions on the skin, but it may also serve to *modify* them, sometimes in a very puzzling manner. It must also be borne in mind that not infrequently a patient may present more than one eruption at the same time; thus, I have myself shown and lectured on a patient who exhibited no less than

five distinct and different cutaneous affections at once. Therefore it is not at all unusual for the disease we are considering to occur in connection with others, and to modify their appearance to a greater or less degree.

Mention has already been made of dermatitis seborrhoica simulating *psoriasis,* and it not infrequently happens that it will occur in the same subject and modify the eruption very materially; when the dermatitis seborrhoica has been removed by proper treatment the psoriasis may persist and exhibit its ordinary features. The same is true of some other eruptions.

It will be remembered that the disease we are considering was formerly called *eczema* seborrhoicum, and was isolated by Unna from the mass of cases which had hitherto passed under the name of chronic eczema. It is therefore very closely related to eczema, and has sometimes been spoken of as "parasitic eczema"; some have denied its existence as a distinct disease and believe it to be a seborrhea on an eczematous basis.

It is, therefore, very readily understood how dermatitis seborrhoica and eczema may modify each other; the former may give a greasy character to many of the lesions, and the latter may furnish vesicles, moisture and thickening, with much greater itching than belongs to the former. It is, therefore, often necessary to treat certain parts with the mild antiparasitic remedies suitable for dermatitis seborrhoica, while the eczematous portions require quite different treatment; sometimes an eczema which has proved rebellious will yield well when the seborrhoic element is recognized and appropriately treated.

Some of the eruptions of *syphilis* have been observed to be much modified by the presence of dermatitis seborrhoica, which gives a greasy character to the scales; it may also give a certain amount of itching, which, not belonging to syphilitic lesions, may obscure the diagnosis.

Finally, dermatitis seborrhoica forming almost ten per cent. of miscellaneous cases of diseases of the skin, in private practice, and coming next to eczema and acne, and about equalling syphilis in frequency, is always to be considered and reckoned with, as it may simulate and modify many other eruptions.

Mention has repeatedly been made of the parasitic nature of the disease under consideration, and a few words will make its nosological position more clear. It is not actively contagious, although it is believed to be caused by the presence of one or more microorganisms; these, however, are not of the grosser varieties, as in ringworm, favus, and tinea versicolor, but belong to the forms of cocci and bacilli, requiring high powers of magnification. As already stated, the exact microorganism causing the disease has not been wholly agreed upon by observers, although there have been many working to determine the question. Inoculation tests with cultures have not, thus far, yielded the hoped for results, although some observers have reported a certain proportion of successful inoculations. Some of the difficulties in the work can be imagined when we remember that Unna[5] describes twenty-three varieties of cocci found in eczema, in addition to a number of varieties of bacilli found by himself and others.

It would lead far beyond proper limits to attempt even briefly to summarize the investigations made on all sides, the recent views of Sabouraud,[6] however, make the subject fairly clear. He regards dermatitis seborrhoica as distinct from seborrhea, as he understands it, due to a seborrhoic microbacillus, causing calvities. The pityriasis, which precedes dermatitis seborrhoica, is due to the microsporon of Malassez, and the scales become greasy by a second infection of cocci, even before the advent of the seborrhoic microbacillus. Unna formerly claimed what he called moro-cocci as the sole cause, but more lately has recognized that there is probably a multiple infection; he, however, lays stress upon the participation of the coil glands in the disease, rather than the sebaceous glands.

Treatment.—Most writers emphasize the local treatment, quite to the exclusion of general and internal medication, and, indeed, it must be granted that the latter alone and unaided has relatively little direct influence on the eruption. There is, of course, no internal specific for the disease; arsenic has little or no influence. But, on the contrary, with the universal presence of microorganisms, and of such a low grade of infectivity, and from analogy in regard to other infectious diseases, it is unreasonable to suppose that the soil, or the vitality of the tissues, has nothing to do with the disease. As in tuberculosis the microorganisms certainly find their opportunity for activity in a suitable soil, and constant experience shows that dermatitis seborrhoica flourishes under certain deranged or depressed states of the system and tissues. In innumerable instances I have heard patients declare that with the advent of dyspepsia the eruption increases and the hair falls.

It is well, therefore, always to pay careful attention to general treatment, including hygiene, diet, and proper internal medication; and these along the lines belonging to eczema, to which the disease under consideration is closely allied, all of which need not be detailed here. For although the eruption is relatively amenable to proper treatment, thoroughly carried out, I am confident that the results are more permanent when perfect general and local measures are obtained.

The local treatment varies often with the patient, and with the location and the character of the eruption. Upon the scalp lotions are far more agreeable and feasible than ointments, and except in specially rebellious cases the latter are not often required. The lotion I most frequently employ is composed as follows: ℞ Resorcin ʒi-ʒii, Spts. vini rectif ʒii-ʒiv, Glycerin ʒii-ʒiv, Aquæ rosæ ad ʒiv. The amounts of alcohol and glycerine may be varied according to the effect, in order not to cause the hair to be too sticky. This is to be applied with a medicine dropper, morning and night, in such a manner that the entire surface of the scalp is dampened with it, the lotion being well rubbed in with the tips of the fingers as it is applied. Occasionally the head should be well shampooed with green soap tincture, and dried with heated towels, the lotion being well applied directly thereafter. Sometimes after the scaling belonging to the eruption is checked, this resorcin lotion, if too strong, will produce a scaling of its own, the flakes being in quite large pieces of thin epidermis, penetrated by hairs. This is no contraindication for its use, but the strength should be lessened. In some cases equal parts of chloral hydrate and resorcin act better than the resorcin alone. Formalin may also be added with advantage in rebellious cases.

Upon other surfaces the treatment varies somewhat according to the condition of the skin, and the location. While resorcin and sulphur are the two mainstays of local treatment, in the more acute conditions they may prove too irritating at first, and that suitable to the acute stages of eczema will be required. In the more dry, scaly conditions about the ears and face it is often very satisfactory to use the lotion just advised for the scalp, allowing it to soak well in, and when dry applying a trace of some

soothing ointment, or one with from three to six per cent. of resorcin added to it.

Upon the chest a resorcin and sulphur ointment (℞ Pulv. resorcin ʒi-ʒi, Sulph. precip. ʒi-ʒi. Ungent. aquæ rosæ ʒi) generally succeeds very well; a little carbolic acid, one or two per cent., often aids the action. Salicylic acid, as in Lassar's paste (℞ Pulv. acidi salicyl. ʒss; Pulv. amyli ʒi, Zinci oxidi ʒi, Vaselin ʒi) is often very serviceable. Also white precipitate ointment, diluted about three times, with a trifle of carbolic acid, acts promptly. It is rarely necessary to use very strong measures, although some writers speak of chrysophanic acid and the strong mercurials. Sometimes for the itching a certain amount of ichthyol, oil of cade, or tar ointment may be added with advantage.

In conclusion, dermatitis seborrhoica is an eruption which should be recognized, for it forms about one-tenth of the cases which come to a dermatologist. To mistake it for true eczema or psoriasis often involves needless anxiety to the patient and a treatment which will not be efficacious.

Proper local treatment is all essential for its removal, but for the best results a certain amount of reconstructive treatment is necessary, that the skin may not furnish such a suitable ground for the growth of the microorganisms found in it, and believed to be of etiological moment.

PROSTATECTOMY.*

By REGINALD HARRISON, F.R.C.S.,
LONDON.
PAST PRESIDENT OF THE MEDICAL SOCIETY OF LONDON.

It is hardly necessary for me to remind this Society that for some years past no practical subject has occupied surgical attention more than that having for its object improvement in the treatment of some forms of prostatic hypertrophy when it occasions serious obstruction to the natural expulsion of urine from the body. It may now be said that a stage has been reached in the history of these endeavors when by the continued though somewhat disconnected efforts of many colleagues, past and present, results have been obtained which have proved of great advantage in this class of diseases and distinctly marked surgical progress.

Though presenting an academic interest I do not propose referring to the somewhat warmly contested subject of the prostatic capsule, and I shall, therefore, confine my remarks to clinical matters.

The surgical treatment of prostatic obstruction, as it occurs in the enlarged or adenomatous gland, may be discussed under three headings: (1) By catheterism alone as practised by the surgeon or the patient himself, (2) by perineal, and (3) by suprapubic prostatectomy. The first method we are not directly concerned with this evening further than to remark that when it suffices for the wants and comfort of the individual the necessity or expediency for the removal of the prostate is not likely to arise. Much more can now be done by strict antiseptic precautions to keep persons within this limit, and there can be no question that many have thus been able to enjoy long and useful lives without taking the risk of an operation such as the removal of the prostate entails, whatever the degree may be. Though fully recognizing the force of this consideration, which has had prominence given to it by Mr. Buckston Browne, Mr. Herring, and others, there can be no doubt that it is not possible to keep all prostatic cases within these limits.

Difficulty in the use of the catheter, pain, frequent and unrelieved desire, the continued formation of vesical stone in spite of its repeated removal by lithotrity, hemorrhage, broken sleep and unrest, cystitis and offensive urine, in addition to other local and general states of sepsis represent conditions which, when persistent, no catheter even with its modern accessories can adequately abate.

It is in cases coming within this category that prostatectomy, using this term in a general sense, has been followed by striking and beneficial results. Opinions are divided as to the respective merits and their application of the perineal and suprapubic methods, and it is to this point I wish this evening more especially to direct attention.

Perineal prostatectomy has for some years been largely practised both in France and in America, but hitherto has not found much favor in this country. It is, I believe, of only limited application, and in my own practice has been almost entirely confined to some partial removals of the gland. For instance, by this route pendulous outgrowths of what is known as the middle lobe of the prostate, which may act as a ball-valve and thus obstruct micturition, may be dealt with with satisfactory results.

Again, this method may be utilized for the enucleation of large isolated unilateral adenomas of the prostate, such as those occasionally met with in the course of perineal lithotomies, on the lines advocated in a paper I read before the Royal Medico-Chirurgical Society in 1882.

Complete extirpation of the prostate can be effected by the perineal way, and many excellent results have been obtained and published by Albarran of Paris, Young of Baltimore, and other surgeons. Amongst the advantages claimed for this method of operating is that the ejaculatory ducts may be preserved intact. I do not, I confess, see where this comes in when the object of the proceeding is the complete removal of the prostate, which is generally regarded as a genital gland.

I have reason to think from cases that have come under my observation that some degree of incontinence of urine is not very uncommon after a completed perineal prostatectomy, in this respect resembling what sometimes happened in the days when lateral lithotomy was commonly practised. This casualty was then considered due to a too free division of the prostate and sphincter of the bladder, and the detriment invariably proved of a permanent nature.

Reviewing his experience of seventy-three patients operated upon by him by median perineal prostatectomy, Dr. George E. Goodfellow of San Francisco makes the following statement relative to incontinence of urine and this operation: "Usually at first complete control of the bladder is regained, but afterwards, when the patient begins to get about, a partial incontinence supervenes, that is to say, there is inability to retain urine when the desire to urinate comes, with some dribbling afterwards, and if the patient becomes tired there is actual incontinence. In a number of cases this has lasted

* Introduction to a Discussion on Prostatectomy, at the Medical Society of London, May 8, 1905.

about four months, but usually in men of about seventy" (*Journal American Medical Association,* December, 1903). Other surgeons record a somewhat similar experience.

In estimating the value of perineal prostatectomy I do not think I can better express my own views upon this point than in the words of Dr. William White, of Philadelphia. In his review of these proceedings, after describing Mr. Freyer's method, he says: "Past experience does not justify the expectation that the results of prostatectomy by the perineal route will compare favorably with those of total enucleation" (*Annals of Surgery,* December, 1904).

Turning now to the most recent development of *suprapostatectomy,* as practiced by my colleague, Mr. Freyer, I again find myself in agreement with Dr. White, who speaks of it "as the operation of choice in the majority of cases." It will hardly be necessary to point out in detail the many advantages connected with this method of operating.

In the first place, the operation may be completed with a knife, aided by the fingers, in a very few minutes. This is due to the bladder and prostate being approached from their most accessible position where there is little or no risk of encountering hemorrhage or of permanently damaging the sphincter or retentive apparatus of the bladder. The latter is, so to speak, out of harm's way, as the results of this operation amply testify.

There is no call, when operating by the suprapubic route, for the ingenious instruments, such as those devised by Dr. Parker Syms of New York and Dr. Young of Baltimore, for drawing the prostate down within reach of the operator's finger, as is the case when the gland is approached by the perineal way.

There is another consideration relative to the technique of the operation, which is of much importance. If you examine a number of specimens of the prostate removed entire by suprapostatectomy a certain proportion will be found—I do not say all—where the prostatic or even membranous urethra has been destroyed or torn across in the course of the enucleation of the gland.

This circumstance has not infrequently called forth the comment that a urethral stricture of a cicatricial kind must necessarily follow. Such, however, contrary to all expectation and experience derived from the observation of other lacerations and ruptures of the male urethra, in whatever part of the canal occurring, has not been the case.

The explanation for this I offered in the Lettsomian Lectures I had the honor of delivering before this Society in 1888. I then endeavored to show, in discussing the cause of traumatic urethral stricture, that the density and contractility of the scar left after a complete or partial rupture from violence or laceration of the male urethra, was in an inverse ratio to the direct drainage provided for the wound. Where the latter was ample and free, as after well-planned surgical incisions of the urethra, for instance, by perineal section or for lithotomy, no stricture followed; whereas, on the other hand, after casual wounds, where no drainage was provided, or it was imperfect, a dense contractile stricture of the urethra at the seat of injury invariably followed.

No more striking evidence of the completeness of the bladder drainage in suprapostatectomy can be found, I believe, than in the fact that though the prostatic and membranous portions of the urethra are liable to, and often do, receive damage, yet hitherto we have had no sufficient evidence that stricture follows entire enucleation.

In selecting the perineal in preference to the suprapubic route, too much credit has been attached to a belief that the former affords better drainage than the latter, and thus favors a more rapid convalescence. I have never found difficulty or delay in healing with the suprapubic route provided that the drainage was sufficiently ample.

In two of my earlier cases of supraprostatectomy perineal urine drainage had been previously and temporarily provided for urgent suppurative cystitis and retention of urine, but no advantage followed this preliminary so far as the healing of the prostatectomy wound was concerned.

Vesical Stone and Supraprostatectomy.—There yet remains to be mentioned a still more cogent reason for selecting the suprapubic method when the prostate from its size, or for other reasons to which I have referred, seriously obstructs the natural function of the bladder.

With a large prostate present it is quite impossible to determine certainly in every instance, by any other means than by freely opening it in front, what the bladder may contain in a narrow-necked valvular sac. Putrid urine or an undetected stone not infrequently occupies these receptacles.

The sound, the cystoscope, the *x*-rays, and digital exploration by the perineal route have frequently failed to detect these and other sources of serious bladder infection and diseases which are not uncommon sequences of obstruction in front.

How often has it happened that a supraprostatectomy has also been the means of bringing to light unsuspected stones contained within saccules and pouches of a presumed healthy bladder. Nor is it uncommon to find, as age advances and the prostate enlarges, the obstruction thus caused "traps" concretions and small stones which would otherwise escape naturally, and detains them for further increase in size within what Mr. Buckston Browne so well described some years ago as the postprostatic pouch. These considerations are of much importance in determining the precise nature of the operation that should be selected for the removal of the prostate.

In making this reference to supraprostatectomy in cases where vesical stone is known or suspected to coexist with much enlargement of the prostate, I do not think it is at all likely to supersede lithotrity in cases of stone occurring for the first time, but when stone in the bladder constantly recurs with this condition an additional reason is furnished for selecting supraprostatectomy in place of repeated operations by litholapaxy alone.

Within the last few years I have met with several instances where vesical stone recurrences have apparently been stopped and a normal state of the bladder substituted after the prostate has thus been removed. There can be no doubt that in many instances the enlarged prostate proves to be the determining cause of stone in the bladder, as well as of its recurrence.

Partial supraprostatectomies have not, on the whole, proved a success. Instances are recorded by Mr. Freyer where, after partial removals in this way, he subsequently, after varying intervals, enucleated what had been left behind by previous operators with good results. And by this is meant that not only was the cause of obstruction removed, but the natural function of the bladder was restored.

I have a clear recollection, at a meeting of the British Medical Association in 1889, of seeing a number of patients, not less than twelve, upon whom Mr. McGill had operated by supraprostatectomy, together with the specimens removed in each instance. Though many of his cases were as successful as could be desired, others fell short of this, so far as the restoration of bladder function was concerned.

I feel sure his cases, as well as those of others, might have been divided into two classes: first, those where the enlarged gland was, to all intents and purposes, removed; and secondly, those where the extirpation was only partial. In this distinction will be found the explanation for the different results that followed then and may be expected now after the latter.

Enucleation with the finger alone, as now practiced, has greatly simplified the process of complete removal and has rendered more secure that which was, to some extent, a matter of chance. Had this distinction been recognized earlier and failures traced to their proper source, I have very little doubt that McGill's operation would not have comparatively fallen into disuse. The partially successful cases seemed at that time to discount largely those where success was complete.

I need hardly say I refer to this point not for the purpose of minimizing in any degree the originality of Mr. Freyer's work, but for illustrating the wide difference in results between partial and complete removal of the gland, however effected.

Mortality.—I will say a few words in reference to the mortality attendant upon the two forms of prostatectomy under discussion. I am not disposed to think there is much difference in this respect between them. I believe, including all causes of death, this is somewhere about 10 per cent. Probably it is rather less with the perineal operation. I have no doubt this percentage might be considerably reduced in many instances by an earlier prostatectomy, and by the exclusion of malignant and other unsuitable cases where the operation has to be undertaken for distinctly palliative purposes. The fact that these operations have been so largely successful, often under very adverse circumstances, must find due weight when considering their adoption and selection.

Preventive Treatment.—I would add in conclusion that though many of the difficulties connected with advanced forms of prostatic obstruction may now be considered as within reach of successful treatment by operation the subject cannot be regarded as ending here. There remains a large field for further investigation which is still comparatively unoccupied.

I should not be doing justice to much work that has been done during the past decade, more particularly on an occasion like this, without a passing reference to this matter.

It is impossible to go through the published records of orchidectomy and vasectomy without recognizing the influence that these processes frequently exercised, and are distinctly stated to have so done, in arresting and aborting prostatic overgrowth. I do not say that either of these operations is capable in itself of removing atrophy, or otherwise, the large masses of prostatic tissue which we are becoming familiar with, as figured in the pages of our journals.

But when I look at instances of vasectomy, for example, operated upon as far back as eight to ten years ago, when the earlier forms of prostatic obstruction appeared to be imminent, and when I see that the patients are now alive with their health and energy unimpaired, it seems to me that evidence of this kind relative to the whole subject of prostatic hypertrophy and its prevention should not be entirely disregarded.

Facts will be found amongst these records which are capable, I believe, of being further utilized without minimizing or detracting from the importance of those measures which I have thus endeavored as briefly as possible to place before you for discussion this evening.

THE IMPORTANCE OF EARLY RECOGNITION OF SUPPURATIVE EAR DISEASE.*

By ALICE G. BRYANT, M.D.,
BOSTON.
OTOLOGIST AND LARYNGOLOGIST TO THE NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN; OTOLOGIST AND LARYNGOLOGIST TO THE POPE DISPENSARY.

It seems superfluous to note here the anatomy of the temporal bone, other than to recall the graphic description Professor Politzer was wont to give during one of his lectures. Gracefully lifting the temporal bone by the styloid process and turning it so that it could be seen by all his hearers, he would slowly and forcibly utter the following words: "The temporal bone has four sides, the outside is bounded by life, from which there comes through the opening of the external auditory canal one form of our appreciation of what life means; on the other three sides this bone is bounded by death."

The scope of this paper is not to present an exhaustive survey of the subject, but rather to state such facts as would be of special interest to the general practitioner from the otologist's viewpoint.

Suppurative ear disease is more prevalent than the general practitioner is apt to believe from actual experience. As to its frequency, various authorities agree that from 30 to 35 per cent. of all ear diseases belong to this class, 5 per cent. belonging to the acute, and the remainder to the chronic.

In the majority of cases, suppurative ear disease is the cause of cerebral abscess and other intracranial complications. Notwithstanding the decided advance made in otology from the pathological and symptomatological point of view in the past decade, and the brilliant results in surgery in the suppurative diseases of the ear and the outlying structures, the annual percentage of deaths from this form of ear disease is still large—larger than it ought to be in the light of our modern methods of diagnosis and treatment; or from the otologists' outlook suspiciously small when we consider the late detected cases that die from acute or chronic suppurative ear disease, or die from some intracranial disease depending primarily upon the ear disease.

We may justly claim that suppurative condition of the middle ear is the most important of all diseases of the ear, not alone from its frequency, but from its serious and dangerous results upon the ear and the parts adjacent, and upon structures even more remote—results that involve life itself. It is not unusual to find that patients have been subject to purulent ear trouble for years, with no disturbing symptoms, and have become quite used to it, for pain is not a marked symptom in chronic suppurative ear disease, except where there is an exacerbation of the trouble; and, if such exist, we must be on our guard for extension of the disease. The slight discharges may be inconvenient, but they are ignorant of the possible dangers of a suppurative middle-ear trouble and thus have not sought treatment. Deafness may be marked in one ear, but perhaps not until both ears are affected will they seek treatment. A subsidence of the discharge may deceive the patients into a perfect security, and all may go well until they have a chill, or chilly sensations, or sudden pain, or sudden rise of temperature; then we should be correct in deciding that there was an extension of the process that may prove possibly to be either a thrombosis of one of the sinuses, meningitis, cerebral involvement, or even pyemia. In other cases, relief is not sought until the derangements in the functions of the ear interfere with

* Read by invitation at the twenty-ninth annual meeting of the Alumnæ Association of the Women's Medical College of Pennsylvania, held in Philadelphia, May 19 and 20, 1904.

the ordinary affairs of life. These inflammations often come on so insidiously that irreparable destruction of important tissues occurs with caries or necrosis of the bone. The ossicles comprising the bridge of bones, especially the incus and malleus, are usually the first to become carious and thus this pathological condition extends affecting the walls of the middle ear.

We know how thin at times is the bone separating the middle ear from the brain and important blood-vessels and nerves; we also know that there may be a dehiscence in the bones at certain points, for instance, over the facial nerve, jugular vein, internal carotid artery, semicircular canal or in the attic roof. Thus it is our first duty to stop the discharge. The overlooking of the earlier symptoms of suppurative tympanic disease and the neglect of treatment at the time when it could be of value is one of the most numerous causes for the unfavorable prognosis that must be given when the patient seeks advice. Almost all forms of chronic suppurative otitis may be considered as a sequel of an acute middle-ear suppuration. The frequency with which infants and children suffer from suppurative ear disease is due largely to inflammatory troubles in the nose and nasopharynx, especially to the presence or swelling of the pharyngeal tonsil, as someone has described it, a "hotbed for the retention and development of infections." We can easily see how bacteria may thrive and multiply in the inflamed mucous membranes.

Adults are less subject to this form of ear trouble, due in part to the absence or lessening of this hypertrophied tissue at the vault and because they are commonly thought to be more easily and efficiently treated; while in fact, an infant's ear yields to treatment more quickly than that of an adult. Meningeal symptoms can be better controlled, good drainage secured and the ear better cleaned, because there is no maze of mastoid and aberrant cells. It may not be amiss to state that a very small speculum should be used in examining an infant's ear. Always warm the speculum and gently draw the ear down and out. The ordinary infants' specula usually found in the instrument stores are too large—they would bother even a specialist, and the less experienced would not succeed in peering beyond the entrance of the external auditory canal.

An acute ear may develop into a chronic suppurative ear from the virulence of the infection or lowered vitality of the patient, by neglected or improper treatment, or perhaps from the fact that the symptoms are soon ignored or forgotten by the patient. I am reminded of a case that I was called in to see a few years ago with the diagnosis of typhoid malaria. A slight discharge had drawn attention to the ear, and with reflected light, speculum and delicate silver ear-probe, a large perforation was found in the membrane and the probe passed upward through an opening in the attic-roof to an extradural abscess. The symptoms pointed to a cerebral abscess, which was verified by a subsequent operation.

Just here I would emphasize the value of becoming as familiar with the use of the head mirror, speculum and delicate silver ear-probe as with the use of the stethoscope, and of making it a practice to examine the ears and also the nose and throat of all patients, especially of infants and children. For exanthematous diseases, scarlet fever, measles, and even smallpox and nasal diphtheria, give rise to a destructive and obstinate type of the disease. Epidemic influenza, in which there seems to be a special tendency to mastoid inflammation, pneumonia, bronchitis, typhoid fever, malnutrition, tonsillitis, mumps, phthisis, malaria, diabetes, and acute or chronic sinusitis, are among the predisposing causes; and also, from a clinical standpoint, the direct introduction of water, not sterile, through the eustachian tube by means of the nasal douche, or the "sniffing up" of water through the nares. It is well to speak of the nasal bath rather than the nasal douche. Clinically one must remember the ease with which a solution in douching an infant's ear finds its way through a perforated drum into the wide eustachian tube and into the throat and is swallowed, or even passes into the larynx. One should be careful in the choice of fluids thus used, for more than one case comes to mind when corrosive sublimate solution was employed in this way with serious results. A gastroenteritis in an infant or child may be due to a suppurating ear, for we have many times seen a drop of pus exuding and even dropping from the pharyngeal end of the eustachian tube, or the pus may pass along the side of the tube into the tissues at the back of the pharynx or in the neighborhood of a tonsil, resulting in a pharyngeal abscess. We may have a septic pleurisy or pneumonia, septic synovitis, or metastatic abscesses develop. A well-known otologist states that "obscure illnesses in young children, consisting of feverishness, irritability, and symptoms of cerebral disturbance, are often explained by the ultimate appearance of a discharge from an ear."

Inflammation in an infant's ear should not be overlooked, and our first attention be drawn to it by seeing a drop of pus appear at the opening of the external auditory canal, a swelling develop behind the ear, or by the appearance of such symptoms as will occur when the pus in the middle ear, not seeking the usual routes, has entered the brain cavity, probably through the petrosquamosal suture. How many times such a condition is attributed to dentition, worms, gastritis, pneumonia, or meningitis! We have been called to an infant in convulsions that were a reflex symptom of an inflammation of the middle ear.

In acute conditions of the middle ear in infants, there may often be no pain or temperature to draw attention to the ear, and thus importance is laid upon the general condition and the ear is often overlooked. Or, in pneumonia, when the lungs are clearing but the temperature, pulse, and respiration suddenly change in character, it has been asked if the ears could cause such a condition, and on examination there was found a drum red and bulging. Malnutrition due to disturbances of the gastroenteric tract or to luetic causes, tuberculosis, or malaria, commonly develops an acute or chronic suppurative ear trouble in an infant or child. Had frequent examinations of the ear been made in every case as a routine practice, the inflamed, swollen, or bulging drum would have been seen, and thus mistaken diagnoses would have been avoided.

The nasal cavities and their accessory spaces, the nasopharynx, pharynx, tonsils, and teeth of all patients subject to acute or chronic suppurative ear trouble should be put in the best possible condition and all abnormal tonsillar and adenoid tissue be removed. Do not overlook the general health of the patient, but pay attention to the constitutional treatment, as this in itself has a most favorable effect upon the ear trouble. We are all familiar with the extreme prevalence of "common earache" in children. Abortive measures may allay the symptoms and cut short the attack, but more severe cases, with streptococcic infection or mixed infection in spite of treatment, will go on to the formation of pus. We have all seen cases of purulent otitis, sudden in onset and severe in symptoms, where streptococcic infec-

tion predominated, for in acute suppuration of the middle ear, the mastoid has shown evidence of involvement by the second day, and the attic and antrum have become infected within a few hours.

The following measures have given good results. It is such treatment as will reduce the inflammation and lessen pain. Douche the ear gently every two hours with one or two quarts of a sterile normal salt solution as warm as can be borne, to be followed by a hot water bag or a hot salt bag. Give one grain of calomel in 1-10 grain doses and repeat as necessary. It has a most favorable effect, especially if given at the very beginning of the attack. Use cleansing and astringent washes for the throat and cleansing sprays for the nose. Caution against too forcible blowing of the nose, or blowing both sides of the nose at once. Have the patient remain in bed until the acute symptoms have abated. The bromides or phenacetine may be given, but with caution, and only for a few days. Avoid all opiates, as they mask the symptoms. The following ear drops, as suggested by Dr. Bacon, have afforded relief: ℞, sulphate of atropine, grs. ij; boric acid, grs. x; glycerin, ℥i; water, ℥i.

As a rule, do not use applications or instillations of remedies to the external auditory canal and drum membrane to relieve the pain—they are generally useless. The sweet oil and laudanum, and sweet oil and paregoric so much in vogue, and other numerous household remedies are mentioned but to be condemned. As we have said, such remedies are generally useless; more time is thus taken to clean the external auditory tract previous to an incision of the drum; and, if spontaneous rupture occurs, the middle ear may become infected from the unclean condition of the external auditory tract.

Do not wait for bulging, do not wait for a spontaneous rupture of the drum, but produce an operative incision and thus avoid involvement of the upper part of the middle ear, for such cases invariably become purulent and yield slowly to treatment. We emphasize the importance of an early paracentesis or incision, in fact within the first few days of the onset of the middle ear trouble, whether pain is present or not. We are often asked if the hearing will not be affected by a paracentesis. There is a normal degree of hearing following these cases of early surgical incision, but where a spontaneous rupture occurs the outlook may not be as favorable.

In influenza it is decidedly unwise to delay before incising, for the condition may be lessened by a prompt recovery by such a very early procedure. The drum may be thickened or fibrous, and the pent-up pus may seek another path that will involve dangerous regions, or a chronic condition may supervene—possibly all might have been prevented had the incision been made early, at a time when the secretion was serous; and in our preventive treatment, we must aim to keep the secretion serous. As a preliminary step, the auricle, the canal, the drum, hands of operator, and knife, should be made sterile. A diamond-shaped knife is used. In making an incision in an infant's drum, avoid touching the inner wall of the middle ear, for we must remember that the round window lies directly in the path of the knife. Make a semicircular cut in the drum proper in its posterior half, beginning below the posterior fold away from the stapes, and incising obliquely to its radiating and circular fibers, so as to avoid an early union of the edges. Where the attic is involved, point the knife upward at the moment the incision is begun, and cut through with one sweep of the knife the numerous connective tissue folds. Avoid grazing the ossicles, withdraw the knife slightly on approaching these, and then sink again into the swollen tissues of the middle ear until the semicircular cut is completed. It will be well to use primary anesthesia, especially in nervous individuals, for the operation is an exceedingly painful one and the patient may already be exhausted from the excruciating pain due to the middle ear trouble; or, if an anesthetic has not been employed, the immediate application of moist heat in the form of compresses will relieve the pain produced by the paracentesis. After the bleeding has ceased, thus greatly relieving the congestion, and the blood in the canal has been removed, a wick of sterilized cotton or gauze is loosely placed in the canal for drainage and is capped by another piece of sterilized cotton placed in the concha to relieve the drainage from the wick. By this means we avoid infection from without, as might happen should the non-sterile fingers of the patient touch the cotton wick. Our treatment must aim to prevent the entrance of bacteria from without and prevent the multiplication of those within. Avoid over-treating the ear at this stage by douching, and irritating instillations. The outer cotton is changed whenever it becomes moist and the cotton wick may remain in for 12 to 14 hours, when another piece is inserted by the physician, who examines again the drum and canal, to keep watch of the ear condition.

This treatment is followed until the discharge grows less and is thin enough to be absorbed by the wick, and stops, as it will in uncomplicated cases at the end of a few days or two weeks, or, at most, under three weeks. Should the discharge become purulent and thick, and the ear fall to the care of a non-medical person, it may be well to have the ear frequently syringed in the form of a douche, using a weak solution of boric acid and sterile water, as warm as can be tolerated; then the ear is allowed to drain for a few moments. It is soothing to the patient and helps to reduce the inflammation.

A word as to the importance of submitting the discharge to a microscopic examination in all cases of middle-ear suppuration; whichever microorganism predominates will give the type. If the streptococci, we shall without doubt have serious complications. It is interesting to recall the statistics that have been made at the New York Eye and Ear Infirmary: (1) Those cases showing staphylococcic infection almost all recovered, requiring no operation. (2) Those cases showing pneumococcic infection, 50 per cent. recovered, requiring no operation. (3) Those cases showing streptococcic infection, almost all required an operation.

By inspection see that the perforation in the drum does not prematurely close as it may do in 24-48 hours, and require to be reopened, or that it does not become clogged with a mucopurulent or purulent mass. If the paracentesis has been well done under an anesthetic, the cases are exceptional where the operation must be repeated.

When the inflammation is very marked, the artificial leech may be used. Apply it in front of the ear. If used over the mastoid process, it would mask the mastoid symptoms by the swelling produced. For the same reason, do not use applications over the mastoid for lessening the pain, that will redden or irritate the skin. Often we do not meet the patient until the acute inflammatory symptoms have subsided and deafness or slight discharge have caused them to seek advice. Examining the drum, we have found it red and edematous, with a pinhole perforation or with a perforation only seen on performing Valsalva's inflation. Mop out the canal with sterile cotton and dust boric acid powder in the canal and over the drum, and recovery will take

place, or we may have to enlarge the opening for a free outflow of the discharge.

It is all important to keep track of the hearing in such cases, for we often have by such tests useful means of deciding how the disease is progressing. If a patient should state that the discharge has stopped and the hearing has grown less, we might anticipate trouble, possibly by a premature closing of the drum; or the fact that the discharge has lessened and the hearing improved would give the outlook of an early recovery.

Mastoid symptoms may develop; and how shall the general practitioner know when the mastoid is involved? Mastoiditis is always secondary to middle ear suppuration. We have already seen what measures should be used to abort the middle ear suppuration. Some tuberculous patients suffer little discomfort. It is more usual to have pain, the mastoid may be tender at one or all of the characteristic points over antrum, tip, or middle of posterior margin of mastoid. In infants this is no guide, for they often cry when touched at other regions of the body, and a sclerosed mastoid may have thickened walls and not be tender to pressure. There may be no elevation of temperature, though the mastoid be filled with pus, and this condition may be met with in acute cases where there is a free discharge. Then, in the absence of pain, tenderness and temperature, we must look for other signs. A careful inspection of the drum and canal wall will find redness, swelling, or sagging of the inner end of the upper and posterior walls over the margin of the antrum, and redness, swelling, or bulging of the drum in its posterior upper quadrant or above the short process of the malleus. It is well to remember that it even may be possible to have mastoid trouble after the canal wall and drum have returned to normal condition. As soon as we are aware of mastoid trouble, we should use cold by means of the Leiter coil or heat by means of the hot-water bag. Should pain and tenderness or redness, and swelling of the antral wall continues for 24-36 hours after free incision of the membrane and the Leiter coil, it would be best to consult with some one experienced in such cases. Too prolonged use of cold by means of the coil or ice-bag will be misleading and mask the mastoid symptoms and cause an early degeneration of the bone. For should such a condition be prolonged, a mastoid operation might be done too late to prevent lateral sinus or brain involvement.

Sometimes a furunculosis of the canal wall may simulate a mastoid trouble. There will be pain and redness in this region, perhaps discharge from the canal, and possibly a swelling over the postaural region. The speculum again will settle the question. It is well to have a speculum made with a long and slender neck, so that it can act as a dilator in the cartilaginous canal and thus get a full view of the hidden membrane and adjacent wall in order to eliminate a middle ear and mastoid involvement. Incise the furuncle only if pointing, and insert in the canal a pledget of cotton dipped in a solution of carbolic acid and glycerine, using a 2-4 per cent. for infants and children and a 10 or 12 per cent. for adults.

When shall a suppuration of the middle ear be considered chronic? After the inflammation has lasted for more than four, five, or six months with or without treatment. Certain cases have the acute stage prolonged for a longer time, but for convenience we must have some fixed date. In chronic middle-ear suppuration we should carefully inspect the drum and the walls of the external auditory canal. Note where the perforation is situated, note its size. It is absurd to treat an ear with a small perforation by the ordinary douching or syringing, for no solution reaches the middle ear, and this is especially true if the perforation be found in Schrapnell's membrane, that is above the short process of the malleus. A chronic suppurative condition situated in this region is most obstinate, yielding slowly, if at all, to the above treatment. In this class of cases, treat by means of the middle ear syringe and catheter or Politzer air douche, or make a counter-opening in the lower part of the drum. For in the attic multiple folds of connective tissue covered with mucous membrane serve the purpose of a good incubating chamber for germs and a reservoir for secretion. Often in old-standing cases, the space is walled off by the inflammatory products from the lower part of the middle ear.

The treatment of chronic middle ear suppuration should aim at stopping the discharge by local and general treatment. Let us emphasize again the importance of removing all adenoid tissue and caring for the nasal and pharyngeal tract. Chronic suppurative ear disease requires patient and careful treatment, insisting upon cleanliness of the auricle and ear tract, preventing further infection and securing good drainage. Aim to improve the hearing and relieve tinnitus and other sounds annoying to the patient. We have various forms of treatment. Those most in use are the dry and wet or a combination of the two. The dry treatment is to be preferred above all others, and should be carried out whenever it is possible to see the patient every day or two, or every few days; but when many days and weeks must elapse between the treatments, the wet method is to be preferred. Whatever method is used, the dry, the wet, or the two combined, we may aid in removing the secretion from the tube and middle ear by using in addition, the catheter or the Politzer air douche.

The dry treatment is simply keeping the auricle clean, wiping out the canal and middle ear if a perforation will permit it, using sterilized cotton wound on applicators by sterilized hands. A little powder is dusted over the drum and canal walls, but a perforation must not be blocked up by the powder, as might occur if a non-medical person were to use the powder. Boric acid powder has given excellent results, but the powder will depend upon the physician's choice.

The wet method is self-evident: simply douching or gently syringing the ear with $HgCl_2$ solution in the strength of 4,000 to 6,000, taking care that none of the solution passes down the eustchian tube; or using preferably a weak solution of boric acid or boiled water; or a combination of the two methods, using the dry method and instilling into the ear a few drops warmed, of any of the following solutions: Bichloride of mercury, 1-5,000; the same with the addition of alcohol in varying strength. A saturated solution of boric acid; the same with the addition of alcohol; or the latter with bichloride, 1-3,000, added. Any of the above-named solutions has a very good effect upon granulations when scant;—if they are plentiful, use nitrate of silver or saturated solution of copper sulphate or zinc sulphate as a thin wash over the surface, after the granulations have been thoroughly curreted. Polypi are only an advanced stage of the granulation process. They may be removed with the ring forceps or snare. Do not mistake for a polyp a protrusion of the swollen tissue of the inner surface of the membrana through a perforation in an acute suppurating ear. Do not try to snare a prolapse of the facial nerve, thinking it to be a polyp, and cause a facial paralysis in so doing, and do not include in your snare the stapes buried in the polypoid mass, while attempting

to remove a polyp. I have seen these mistakes made, and in the last case intense vertigo and nausea followed, lasting for hours. Let the delicate silver ear-probe outline the attachment of all polypi and thus avoid mistakes, and the probe will detect caries of the ossicles or walls. A facial paralysis, partial or complete, may be brought about by pressure or ulceration of the facial nerve in the course of a suppurating ear. It should be quickly dealt with, locally and generally.

To improve the hearing and tinnitus, inflate the ear and use appropriate middle-ear massage. If carried out carefully while the discharge is lessening, we shall improve the hearing, provided the trouble be limited to the middle ear. However, if the labyrinths have become involved, this treatment will be of little value. When the latter condition exists, and is met with early, we may improve it by the use of muriate of pilocarpine. It is well to tell your patient that there is a possibility of the hearing being worse when the discharge has ceased, than when it was present.

In chronic suppurative middle-ear disease, when the drum and the three bones have ceased to be united, due to the destructive process, it would be well to remove all but the stapes, leaving that free, for the capability of vibration is much increased by such an operation, and the hearing will thereby be improved, and remedies can be more exactly applied to the middle-ear walls. The following case will illustrate many points that have been referred to in this paper. It will show that fair hearing may be brought about in a chronic suppurative ear when drum, malleus and incus have been all destroyed. The patient was a young girl of fourteen, who, during an attack of scarlet fever, six years previous, developed a double chronic suppurative ear trouble. The tonsils and adenoids were removed, a deviated septum straightened and the middle ear treated until all secretion stopped: The drum, malleus and incus had disappeared from both ears, leaving the stapes in place, but bound down by adhesions. Hearing showed middle-ear deafness. Whisper heard in right ear, 1 foot. Whisper heard in left ear, 3 feet. Adhesions were removed about the foot-plate of the stapes in right ear, and six months later a similar operation was done in the left. At stated times the stapes were mobilized and cotton drums were used, bringing up the hearing in the right ear from one foot to 16 feet; in the left ear, from 3 feet to 20 feet, and during the last six years there has been no recurrence of discharge, and the hearing has dropped a few feet, to be reinstated by mobilizing the stapes.

How long shall we treat chronic suppurative ears by remedial measures and topical applications? We ought to give a fair amount of time, from two to four or six months of treatment, when, if the discharge does not cease after most careful treatment and the general health of the patient suffers, we must tell our patients of the dangers arising from such a condition and advise an operation. An ear should have ceased discharging for two years, at least, before we can claim a satisfactory result, and no suppurative ear is cured until all secretion has stopped and there is no crust formation. An ear that discharges continually in the presence or absence of fetor, in spite of patient and careful treatment, even though the perforation be large, should be looked upon as a menace to life, and operative measures should then be advised. An ear that has stopped discharging, leaving a free perforation, might be considered as moderately safe, but it would not be a guarantee that there might not develop within a shorter or longer period of time, a renewed attack. We should advise such patients not to allow water to enter the middle ear through the perforation, as it might easily happen in bathing or swimming. At such times it would be well to seal the external auditory canal with sterile non-absorbent cotton. Where an ear has stopped discharging and a new drum has formed, the outlook is most favorable. Where there is a free perforation and the ear has ceased discharging, we should aim to reform the drum. Some of the operations referred to consist of a middle ear, or simple mastoid, or the radical mastoid operation, the latter meaning throwing the tympanic cavity, mastoid antrum, mastoid cells, and external auditory canal into one cavity, and then remove all diseased structures. But to go into the surgical procedures would be beyond the aim of this paper.

THE TREATMENT OF EPIDEMIC CEREBROSPINAL MENINGITIS WITH INJECTIONS (CHIEFLY INTRASPINOUS) OF DIPHTHERIA ANTITOXIN.*

By GEORGE L. PEABODY, M.D.,
NEW YORK

The oldest of all the therapeutic methods is the empirical. It is of necessity crude, for it was based upon undigested and very rough experiment, undertaken often without a knowledge either of the nature of the disease to be treated or of the effect of the remedy to be applied to it. The urgent desire to relieve suffering and cure disease was its incentive; and its prosecution by a sort of groping in the dark through thousands of years, has led to the accumulation of an enormous material, often the result of imperfect observation. In all the immense mass of chaff thus piled up in the centuries, there are a few kernels of wheat which make us grateful even for so very crude an experimental method. Thus modern science has added only details to the empirical methods of treating syphilis and malaria, and even still fails to explain much of what we adhere to in regard to them.

Except in the presence of fully developed hydrophobia I do not think that I have ever been so painfully impressed with a sense of the limitation of our therapeutic resources as during an epidemic of cerebrospinal meningitis. In the rare and isolated cases of hydrophobia the feeling of helplessness is not so complete and overpowering as it is when we find ourselves day after day in the presence of a disease whose course we are unable to modify.

When Dr. Arthur J. Wolff of Hartford told us in January of the pronounced antagonism between the Klebs-Loeffler bacillus, and the meningococcus, we were in the midst of the severest epidemic of cerebrospinal meningitis that most of us have ever been called upon to face; and although we knew a little more of the causes of the disease than our remote predecessors, and had ascertained that in the present epidemic the meningococcus was the sole exciting agent, we felt ourselves as helpless as they had been to cope with it.

Under these circumstances I think we were justified in trying the diphtheria antitoxin, without much hope, certainly, but with the feeling at least that we should do no harm. Accordingly, in the Roosevelt Hospital my colleague, Dr. Jacobi and I, in our respective services, subjected twenty-two cases to the action of this agent. In all but one of these the diagnosis was proved by finding the meningococcus in

*Read at a meeting of the New York Academy of Medicine April 20, 1905.

the spinal fluid. They were all cases of clinically unmistakable cerebrospinal meningitis. Most of them were under eighteen years of age and many of them were young children: a few only having been twenty years old or older.

Many of them came under treatment early in the disease, probably before marked anatomical changes had occurred. All of them were subjected to spinal puncture, and from all of them cerebrospinal fluid was withdrawn. Sometimes this was found to be under abnormally high pressure, but by no means always so. The fluid was usually turbid and distinctly purulent, and in every case but one, as I have said, it contained the meningococcus. It is of interest to know that the fluid may be normal microscopically and sterile in cultures in well-marked, fully-developed cases of the disease. Leube had found this to be the case before. I have seen a fluid normal miscroscopically and sterile in cultures preceded and followed (with intervals of a day or two), by turbid, purulent fluid abounding in meningococci in an unmistakable case of the disease. Thus in any given case the negative results of a single spinal puncture may be misleading.

I have said that many of these cases came under treatment early in the disease. One received his first injection on the first day of the disease; five on the second day; six on the third day; four on the fourth day; and others on the fifth, sixth, and later days.

In all cases fluid was removed by tapping, as I have said. This varied in amount (depending somewhat upon the degree of pressure that it showed), between two drams and an ounce generally, though occasionally more was withdrawn. No marked symptoms followed this procedure as a rule. Occasionally a very dull, apathetic or semi-comatose patient became brighter, and in one instance a transient condition of collapse followed the removal of six drams. The withdrawal of larger amounts never caused unpleasant symptoms.

Of the twenty-two cases four received the antitoxin only subcutaneously, seven received it at different times both subcutaneously and intraspinously, and eleven received it only intraspinously. In only one case did it seem to cause any unpleasant effect. This was a girl of fifteen, and the effect alluded to was an urticaria which lasted several days. She received a single intraspinous injection of two thousand units and made a steady and complete recovery from the disease.

The doses varied from twelve hundred units to fifteen thousand. Only two patients received but a single dose each. In all of the others it was repeated at least once, and some received four, five, and six doses.

The treatment was begun late in January. Of the twenty-two, eleven have died, making a mortality to date of fifty per cent. Seven of these eleven died before the sixth day of the disease. Of the eleven dead one received the antitoxin on the first day of the disease; three on the second day; two on the third day; three on the fourth day, and only two later than the fourth day. Of the eleven still living, two are entirely well; two others are fully convalescent; five are still under treatment (no longer by antitoxin), with active symptoms and very grave prognosis; and two may be said to be practically moribund.

Thus the mortality of the twenty-two cases, while still uncertain, will go well beyond fifty per cent., and the percentage of recoveries to date is a little over nine.

I am well aware that these figures are far too small to justify any statistical deduction; but it is fair to assure you that there has not seemed to any of us who have watched these cases, any influence for good or evil to be ascribed to the treatment of them by diphtheria antitoxin.

I have been greatly aided in studying these cases and in the elaboration of the facts here recorded by the house physician, Dr. Hans Zinsser, and a very willing and able corps of assistants.

Even now we cannot afford to dispense entirely with the empirical method in therapeutics; but its application by some of us this winter to the treatment of epidemic cerebrospinal meningitis compels the mortifying acknowledgment that we have added only to the chaff accumulated by our predecessors without contributing a single kernel of wheat to the store that we had inherited from them.

A CASE OF LONG STANDING MAJOR HYSTERIA CHARACTERIZED BY A PAROXYSMAL AND FIXED PAIN, MENTAL DEPRESSION, CONFUSION, DELIRIUM WITH DELUSIONS, AND HALLUCINATIONS TERMINATING IN SUDDEN RECOVERY.*

By THEODORE DILLER, M.D.,

PITTSBURG.

NEUROLOGIST TO THE ALLEGHENY GENERAL HOSPITAL; VISITING PHYSICIAN TO THE INSANE DEPARTMENT OF ST. FRANCIS HOSPITAL.

In a paper read before the Neurological Section of the American Medical Association last summer (*Journal American Medical Association,* March 4, 1905) I detailed four cases of major hysteria presenting marked and prolonged delirium as a conspicuous symptom. The mental condition of each of these patients was, for a time, that of profound "insanity." Indeed, the gravity of the mental symptoms were such as to lead me to present the diagnosis of hysteria in a more or less tentative manner. As a further contribution to the study of delirium as a symptom of hysteria I desire to present the following highly instructive case, in which I make the diagnosis of major hysteria with more confidence.

The case is that of a married woman aged now 35 years. The only significant points obtainable in her previous history are that she was unhappily married, had been abused by her husband, and compelled to support herself.

Her present illness began on the night of July 3-4, 1902, when she suffered from severe pains in the lower abdominal region and hemorrhage from the vagina. She was extremely nervous. The explosion of firecrackers and torpedoes in front of her home, in celebration of the "Fourth" caused her to frequently start and spring up in bed. These movements produced gushes of blood from the vagina. Her physician packed the uterus with sterilized gauze and gave her a hypodermic injection of morphia, believing that she was aborting. She rested well during the remainder of the night. The next day her physician was surprised in removing the packing in failing to discover a fetus or any other evidence of pregnancy. The womb was somewhat enlarged, the cervix soft, and the os slightly dilated. There was some tenderness on pressure. The temperature was normal. "Wasting" continued for several days. A few days later the patient returned to her occupation—that of a milliner—although suffering a good deal of pain in the left inguinal region. She had been at work only a few days, when she was suddenly seized with a severe exacerbation of the pain in the left inguinal region, radiating down the left thigh, over the ilium and up the entire

*A paper read before the Pittsburg Academy of Medicine March 7, 1905.

length of the spine. This severe pain lasted some thirty-six hours, and it was only partially relieved by maximum doses of morphine and by inhalations of chloroform.

At intervals of from three to four days to three or four weeks the patient suffered during a period of two and a half years from similar attacks, more or less prolonged and severe. In the intervals between these attacks she suffered from more or less steady but bearable pain in the left lower abdominal region. In one particular attack she exhibited great irregularity of breathing, which was so alarming that her physician, with a colleague, worked over her all night, endeavoring to keep up artificial respirations.

The attacks of pain came on suddenly. Often after the physician had left the patient comparatively comfortable he would—within a half hour—be summoned back to her bedside, to find her suffering excruciating agony and screaming aloud, and would have to labor for hours before being able to again restore her to a state of comparative comfort. The patient's temperature was, as a rule, normal, except on a few occasions, and then only slight elevations were observed. Ordinarily her pulse was normal.

At one time during her illness she suffered a good deal from nausea, and for periods of two or three days was unable to retain food in her stomach. She had also occasional periods during which micturition was difficult or impossible for a time.

There were two striking features of these attacks, viz., (1) that in none of them was any visible or palpable alteration in the painful area discoverable, and (2) that muscular tension over the affected area was always far less than would naturally have been expected to result from an organic lesion.

Early in December last (nearly two and a half years after the onset of her trouble) the patient became depressed and somewhat delirious, and on the 13th of the month was admitted to the Allegheny General Hospital, in the gynecological department. An examination of the pelvic organs made by Dr. F. F. Simpson revealed them to be in a normal condition, but was discovered a protrusion of the abdomen at the seat of pain. She was transferred to the Neurological Department and came under my care, and after January 5, and until her discharge, on January 27, she was under the care of my associate, Dr. McKennan, who kindly allowed me to follow the case to its termination.

On admission she was mentally depressed and more or less delirious and confused. She talked of suicide and often got out of bed and attempted to go towards the window. She was emotionally depressed, cried a good deal, but was able to answer questions and to properly orientate herself. She complained of much pain in the lower left abdominal region, which was discolored and apparently somewhat indurated (numerous blisters, mustard plasters, etc., had been applied). Her condition grew rapidly worse. Consciousness became clouded, orientation defective, delusional ideas with hallucinations developed; the tongue became dry in the middle, and later along the sides; insomnia and irregular elevation of temperature developed (100-102). The patient's pulse became thin and feeble. She was much emaciated. Physical examination revealed a sallow, emaciated woman, otherwise it was negative. No sensory phenomena discoverable other than those mentioned. The pain seemed to be in both the skin and underlying structures. The blood and urine were normal.

Shortly after her admission it became necessary to restrain her in bed. Her delusions were to the effect that some great bodily harm might be done her. One day she said: "Sixteen of we girls are condemned to go to the cellar this afternoon." Again she heard terrifving sounds: "Don't you hear that shooting?" Again she said, "Dr. ——— (the interne) is going to take me to the cellar and shoot me and have over with me." "I am afraid I am a nuisance." She gave utterance to many similar expressions. Whenever talked to she would sob. She finally failed to recognize friends and confused their personalities.

Her tongue was somewhat coated upon her admission, and it afterwards became dry in the center, and finally all over the dorsum. She was stubbornly constipated. Her pupils were slightly dilated, equal and reacted to light. Throughout her illness, even when her mental symptoms were most profound, she exhibited great tenderness in the left inguinal region whenever palpated there. But palpation produced only moderate muscular tension, far less than one would expect from organic disease. Shortly after improvement had set in numerous groups of petechial eruptions suddenly appeared in the region of the head and neck, being especially thick just over the posterior borders of the sternomastoid muscles. This eruption disappeared after a few days.

On admission to the Neurological Department, even in the absence of the previous history, but in the light of Dr. Simpson's examination, the diagnosis of hysteria suggested itself to both Dr. Simpson and myself, although the tongue and breath indicated faulty metabolism and autointoxication. When the symptoms were at their height it seemed that the patient would die. With great emotional depression and low muttering delirium, loss of orientation, elevation of temperature to 102 and a dry brown tongue, and with persistent tenderness on the old seat of pain, the diagnosis of hysteria no longer seemed tenable. It was thought that some source of toxic infection might exist in some region other than the pelvic organs. I thought of, among other possibilities, disease of the abdominal muscle. Dr. Gaub, at my request, now examined the patient from the standpoint of the general surgeon, with a practically negative result. I asked him, however, in the presence of the patient, to make an exploratory incision through the tender abdominal muscle. This was on January 2. From that moment, certainly from that day, the patient began to improve, and continued to do so rapidly and steadily, and was within two weeks free from her abdominal pains, vastly clearer mentally, exhibited great physical improvement, a moist tongue, ate and slept well. On January 27 she was discharged, apparently in the best of physical and mental health.

With the progress of the case—it's improvement—the abandoned diagnosis of hysteria was again taken up. I may add that the patient's previous history was obtained about this time, and this only served to reinforce this diagnosis. The consideration of the clinical picture as a whole, its paradoxical character, with the astonishing improvement resulting from the mental impression made by the suggested operation, taken together, indicate the diagnosis of hysteria. I may add that there was much about the patient which can scarcely be described in words which was suggestive of hysteria.

No diagnosis other than that of hysteria presents itself to my mind as offering anything like an adequate explanation for the remarkable onset, course, character, and termination of the symptoms in this case. If the diagnosis of hysteria be admitted, are all the symptoms related to be explained as expressions of this disease? The onset, course, and termination of these symptoms lead me to answer this question in the affirmative; and this answer means that uterine hemorrhage, severe autointoxication,

mental depression, confusion, delirium, and elevation of temperature were among the extraordinary expressions of hysteria in this case.

Even if the diagnosis of hysteria be allowed, it may be argued that the autointoxication and delirium were not hysterical, but rather constituted a complication during the course of hysteria. But whether this view or that which I have expressed above be correct, I believe we have in this case another illustration of the fact that exhaustion is a great underlying cause of hysteria—a point which is too often overlooked. In other words exhaustion and irritability produced both hysterical manifestations and those of toxemia with delirium.

After the patient had recovered her health she recalled many of the events of her illness, even of the period of grave delirium. She attributed the hallucination of the pistol shots to the noise made by the elevator. The contrast between her condition of January 2 and that of January 27, when she left the hospital, was little less than marvelous.

A letter written six weeks later by the patient informs me that her good health continues.

A CASE OF MENSTRUAL URTICARIA.

By D. J. M. MILLER, M.D.,
PHILADELPHIA

In the majority of works on dermatology the general statement is made that functional and organic affections of the female sexual organs are among the causes of urticaria. Some authors are more explicit; Radcliffe Crocker,[1] for instance, who says that some women have urticaria before each period, or at each pregnancy, or during lactation. Notwithstanding these general statements, I have been able to find but few reported cases of genuine urticaria associated with menstruation. Instances of erythematous eruptions, however, and various vasomotor disturbances of the nature of urticaria, but resembling more closely angioneurotic edema, or erythema exudativum, appear with comparative frequency in the literature. Thus Von Linger[2] relates the history of a girl of 16 who, from one to two days before each period, had an eruption of round, red, itching papules which, after the third day, resembled purpura hemorrhagica. Simultaneously there were albumin, blood, and bloody and granular casts in the urine. If the period failed, the eruption did not appear. At the meeting at which Von Lingen made his report, Dobbert[3] spoke of two similar cases. J. Schramm[4] has recorded two instances of erythema exudativum accompanying the menstrual flow, one appearing at the onset and lasting through the period, the other breaking out as the flow was waning. In a third case a widespread urticaria appeared after the application of leaches to the cervix. Similar phenomena were observed by Scanzoni[5] after vaginal examinations with finger or speculum. All of Schramm's patients had chronic uterine disease. Five cases of edematous swellings of the skin associated with menstruation are reported by Ernest Börner;[6] they made their appearance during the flow, or a few days before. In most of Börner's patients the eruption was of the nature of angioneurotic edema, *i.e.* localized edematous swellings, limited in extent and without itching. All were young, healthy girls.

A case of premenstrual eruption, ecchymotic in character, in a healthy woman of 29 years, was observed by Wilhelm Ludwig.[7] The eruption preceded the period by two or three days. B. Stiller[8] has seen an analogous case. The same author has recorded the interesting history of a woman in whom a burning, itching eruption was vicarious of menstruation. The patient menstruated irregularly, often missing three or four periods. With the onset of the flow the eruption vanished, only to reappear after five or six weeks, if, in the meantime, the menses failed to come on. In still another patient, a woman of 45, Stiller observed a "strongly itching efflorescence," resembling acne, before each menstrual period.

From the cases I have cited it appears that ordinary urticaria is the least common of the eruptions occasionally seen in connection with menstruation; also, that these eruptions may precede the flow by several days—as long as eight—and may cease a day or two before the period, or at the time of its appearance, or may continue through the flow, or may occur simultaneously with the flow and last a day or two, or until the latter has ceased. That the eruption in these cases was dependent upon menstruation is shown by the failure of the former to appear should the period be missed. All observers regard these menstrual eruptions as reflex phenomena. The writer's case is that of a girl of 15, who began to menstruate at the age of 12. The periods were, at first, irregular, but for the last two years have recurred regularly every 4 weeks, lasting from 3 to 4 days each time. With the establishment of regularity the attacks of urticaria began. They make their appearance seven or eight days, and cease from two to three days, before each period. Occasionally the urticaria persists until the flow begins, rarely during the first day or two of its course. During the intervals between the periods the patient is quite free from attacks. That the skin affection is dependent upon the menstrual flow is shown by the fact that, owing to a change of residence from England to this country, some eight months ago, the patient missed two periods, and that during these two months she was quite free from urticaria. The girl menstruates normally and regularly, and is perfectly healthy and without physical ailment, other than the constantly recurring attacks of urticaria, which necessarily cause her much annoyance and discomfort. She is of a nervous temperament. None of her sisters, nor her mother, nor any of the members of her father's or mother's family have been similarly affected. The urticaria itself is of the ordinary type, viz., large and small, irregularly-sized wheals, accompanied by burning, itching, and tingling, usually limited to the skin, but sometimes appearing in the mouth; there has never been colic or abdominal pain, or other evidence of the implication of the intestinal, or other mucous membranes.

Papillomas in Syphilitic Child, Occluding Both Nostrils.—Harland reports a case of a colored child, aged 8, in whom soft tumor masses arising from the base of both nostrils obstructed respiration. These dated back two weeks, and quickly disappeared under mercury and iodid, with local applications of silver nitrate. The condition seems due to overgrowth of the papillary layer of the corium, not syphilitic, but apt to occur in those with specific infection. The nose is very seldom affected.—*American Medicine.*

TYPHOID MENINGITIS.

ALTHOUGH the mental and nervous symptoms of typhoid fever occur almost constantly in the severer forms of this disease, they vary extraordinarily in intensity, and the relationship of the nervous symptoms to the pathological lesions is still obscure, although the etiological agent has been discovered. The principal lesion of the nervous system due to the action of the typhoid bacillus is meningitis. Within the last few years six cases of typhoid fever showing meningeal symptoms were studied at the Johns Hopkins Hospital, by Rufus I. Cole, the results of this study being recorded in the Johns Hopkins Hospital Reports for 1904. In all of these typhoid bacilli were demonstrated in the spinal fluid.

It seems convenient according to Cole, to divide the cases of typhoid meningitis into three groups: Cases showing symptoms of meningitis in which no meningeal lesions can be demonstrated, called by the French term *méningisme*; cases in which the causal relationship of *Bacillus typhosus* is demonstrated by its cultivation from the cerebrospinal fluid taken during life or at autopsy, and in which there is no suppuration, called serous meningitis; and cases of purulent meningitis. Exact limitation of the first group is impossible so long as its anatomical basis is unknown. It is known that even in tuberculous meningitis, particularly in the early stages, the exudate is purely serous. The ages of Cole's patients ranged between five and thirty-five years. Headache, mental hebetude, unconsciousness and coma, or restlessness and delirium followed by coma were quite constant symptoms. Convulsions were noted in four cases. Rigidity, spasm, and twitching of the muscles occurred in varying intensity in nearly all. Stiffness of the neck, retraction of the head, and abdominal rigidity were not constant, although they were present in several cases. In one case, nausea and vomiting were marked and persistent. In several cases there was incontinence of urine and feces. Facial paralysis occurred in two cases. Optic neuritis was not noted in any. In some of the cases inequality of the pupils, failure of the pupils to react to light, and strabismus occurred. The reflexes varied. In all of the writer's cases frequent leucocyte counts were made and in none of them did a leucocytosis appear with the onset of meningeal symptoms. In general these symptoms are moderate in severity, and differ in degree only from those commonly seen in cases of uncomplicated typhoid fever. After the onset of marked meningeal symptoms the course of the disease is variable. Lumbar puncture was performed in eight of the cases reported by Cole, and in all of them the fluid was quite clear with only a few leucocytes in the sediment. In only one case could the presence of bacteria be demonstrated microscopically, but in all typhoid bacilli were cultivated from the spinal fluid. The pressure did not seem to be increased in any of the writer's cases. In five of the cases, improvement followed puncture, and in one ultimate complete recovery ensued. In the other cases death occurred later from other complications. Lumbar puncture is important in the treatment of cases of typhoid fever in which marked meningeal symptoms appear, for it may possibly prevent a serous meningitis from becoming purulent. Cultures should be made from large amounts (4 to 6 c.c) of the fluid. In the cases studied by the writer, the cerebral and so-called meningeal symptoms were marked, but they were not sufficient to differentiate the cases. The pathological changes hitherto demonstrated consist in edema, hyperemia, and moderate infiltration of the meninges. The characteristic feature is the localization of the typhoid bacilli in the meninges and spinal fluid. It is probable that wherever the bacilli are localized, at least a beginning true inflammatory reaction exists, and the majority of pathologists now believe that the pyogenic rôle of the typhoid bacillus has been definitely proven.

In this study of typhoid purulent meningitis, various facts were ascertained: The patients ranged in age from four to forty-six years. The symptoms were those of a general acute meningitis. There were no special features distinguishing this form from serous meningitis, although possibly in most of the cases the cerebral symptoms were a little more active. In most of the cases the onset of the meningeal symptoms occurred late in the disease. The writer concludes that it is evident that the localization of typhoid bacilli in the meninges bears an important relation to the cerebral and meningeal symptoms which are observed in many cases of typhoid fever. He is led to believe that the serous form of meningitis is far more common than the suppurative.

In the same publication W. C. MacCallum treats of the pathological anatomy of this complication. After discussing the anatomical picture seen in one of the cases of purulent meningitis, reported by Cole, he says that there is nothing in it quite peculiar to typhoid meningitis, unless possibly the relative abundance of the large, phagocytic cells may be so considered. These occur also in the epidemic cerebrospinal form, in great numbers in the tuberculous form, and also in the various other forms of meningitis produced by *Micrococcus lanceolatus,* the streptococcus, and so on. The recognition of the typhoid bacillus, therefore, as the etiological factor will alone warrant a diagnosis of the condition. The veins in nearly all cases are distended with blood, and many lymphocytes and sometimes the larger forms of cells are seen in this blood. In the arteries the endothelium is even lifted up by masses of cells, and sometimes this proceeds to such an extreme as to obliterate the lumen of the vessel. That writer believes that the polymorphonuclear leucocytes emigrate from the blood-vessels, for they can be seen in all stages as they wander out through the walls of the veins. MacCallum concludes that meningitis may be looked upon as essentially an exudative process in which practically all the

cells are ultimately derived from the blood-stream, with more or less profound modification subsequent to their emigration, and thus the type of meningitis due to the typhoid bacillus is brought into far closer analogy with the other forms of acute meningitis than it would be were it found that the chief alteration was simply a proliferation of fixed tissue elements.

THE PREVENTION OF DISEASE IN ARMIES IN THE FIELD.

A BOOK with the above title, by Major Caldwell, which was recently awarded the Parke's Memorial Prize, is reviewed at considerable length by Dr. A. M. Davies in the *Journal of the Royal Army Medical Corps* for February. The question of preventing disease in the time of war is manifestly of such supreme importance that any expert opinion on the matter is worthy of close consideration. The author of the book referred to shows that enteric fever in the field during the South African war was much more probably caused by soil pollution than by a polluted water supply, and the same may be said as regards dysentery.

As to latrine trenches, Major Caldwell is averse to the practice of digging deep trenches and shows that shallow trenches (not more than one foot deep) are more scientific. In the case of troops occupying a camp for some time, he advocates a pail system of removal. The most important of the author's conclusions are as follows: 1. That apart altogether from endemic causes, certain conditions attendant on field service are potent factors in the production of disease. 2. That among disease-producing factors soil pollution occupies a prominent place. 3. That, although the existence of water-borne typhoid fever is beyond doubt, other factors—notably soil pollution—are of as powerful a nature as the first named in a like direction. 4. That the best means of water purification are not known with certainty. 5. That, as so many cases of so-called simple continued fever are undoubtedly typhoid fever, and as these unrecognized cases are active agents in the spread of the latter disease, means for carrying out the serum diagnosis should be given as wide a field as possible of general applicability. 6. That the prevention of disease in any army in the field resolves itself largely into the question of the disposal of organic refuse. 7. That the spread of epidemic sickness in the field is largely the result of the presence in field hospitals of patients suffering from forms of communicable disease. The author considers that such cases should be treated in hospitals at the base or on lines of communications, and not up at the front. 8. That, with a few common sense exceptions, the excreta of all patients in field hospitals should be sterilized. 9. That so far as is consistent with military exigencies, autonomy should be granted to the medical service of the army as regards sick transport.

In the investigation which took place during the Spanish-American war, with respect to the cause and prevention of disease among troops in the field, by Dr. Vaughan and others, it was shown that soil pollution played an important part in the production of typhoid fever. In the review of the book by Major Caldwell, no mention is made of flies as factors in the spread of typhoid fever. By most writers who have dealt with the Boer war from a sanitary standpoint, flies are pointed out as probably responsible for much of the typhoid fever which prevailed so extensively. Dr. Vaughan held the view that to flies was due much of the sickness from that disease in our last war. It would appear, therefore, that the importance of water as a means of spreading disease among armies in the field has been somewhat overestimated, and that there are other ways in which disease is disseminated of almost equal significance.

SALINE TRANSFUSION AND INFUSION IN MENTAL DISEASE.

IN the *Albany Medical Annals* for April, Dr. J. Montgomery Mosher publishes the third annual report of Pavilion F of the Albany Hospital, for the year ending February 28, 1905. The Pavilion F is that for mental diseases. Dr. Mosher has a good opinion of the value of saline solution in those cases of mental disturbance characterized by a condition of toxemia. He is against the administration of hypnotics in acute cases of mental affection characterized by exhaustion and a toxic state, due usually to irregularities of excretion, particularly of the digestive tract. The writer thinks that the rational treatment of such a condition as to promote elimination, by purging and by the administration of large quantities of liquids by which the activities of the kidneys and skin are stimulated. In regard to the value of decinormal salt solution, he refers with approval to a monograph on "Transfusion and Infusion," in the *Wiener Klinik* for July and August, 1904, in which Dr. Van Amstel reviews the subject and its literature, and he analyzes the following summary of the indications for saline infusion: (1) In extreme grades of anemia, no matter what the cause, as following severe hemorrhages during and after childbirth, in placenta period, after capital operations, wounds, hemorrhages from the stomach and lungs. (2) In severe losses of the body fluids, as in Asiatic cholera. (3) For irrigation of the human organism in (*a*) acute poisoning, (*b*) autointoxication, as the typhoid state, diabetic coma, puerperal fever, puerperal eclampsia, bubonic plague, and uremia. (4) As modified by Landerer by the addition of sugar, in chronic anemia, for artificial alimentation. Mosher adds that in Group (3) should be included the condition of extreme mental exhaustion with autointoxication, of which the symptoms are acute delirium or profound stupor. It is a well-known fact that many cases of mental disturbance are accompanied, perhaps even caused, by a condition of the digestive tract which gives rise to autointoxication. This is especially true in cases of delirium or hallucinations arising from overindulgence in stimulating beverages. Hypnotics have a temporary soothing effect, and are occasionally necessary, but in the long run these do more harm than good. The common sense treatment is to get rid of the toxic substances in the system by means of purging and by stimulating the action of the kidneys and skin.

BOVINE TUBERCULOSIS.

PROFESSOR KITASATO read a paper before the International Congress at St. Louis on bovine tuberculosis in Japan. He described investigations prosecuted under his direction with the object of determining, if possible, the connection between human and bovine tuberculosis. The facts in Japan differ

from those in European countries in that in Japan native cattle are free from tuberculosis, which is confined to foreign cattle and to cattle of mixed breed. Various experiments were undertaken, and the conclusion was reached that bovine tuberculosis plays no part in Japan in the transmission of tuberculosis to man, and that the disease is transmitted solely from man to man. Kitasato is also of the opinion that human tuberculosis is not infectious to native cattle or to those of a mixed breed; he, however, does not infer, as does Koch, that human and bovine tuberculosis are distinct diseases. The London *Review of Reviews,* commenting on the result of Kitasato's investigations, says editorially: "The evidence obtained so far seems to show that the bacilli of human and bovine tuberculosis are temporarily modified forms of one organism, but it by no means follows that bovine tuberculosis is under ordinary circumstances a source of danger to man." In Great Britain and in this country it is believed by very many authorities, and justly so, that bovine tuberculosis is a source of real danger to man. In England it would seem to have been proved time and again that children have contracted intestinal tuberculosis through the agency of infected milk. In any case, the doctrine is a mischievous one which preaches that there is no danger to health from the consumption of infected milk.

Typhoid Fever in Infancy.

At one time it was believed that young children did not suffer from typhoid fever, until it was demonstrated by Rilliet and Taupin, in 1840, that "remittent gastric fever of children" was really typhoid fever. Dr. Otto Grünbaum writes in the *British Journal of Children's Diseases* for April, 1905, an exhaustive article dealing with this subject. The writer points out that Koch has insisted emphatically that cases of typhoid fever are frequently missed in infants, and may become centers of infection, and that, therefore, every precaution should be taken. Dr. Grünbaum considers that as typhoid fever in infancy is often mild and difficult to diagnose, it is wise to look upon all doubtful cases as infectious and to treat them accordingly. Dr. George Carpenter also writes, in the same journal, on the same subject, and remarks that the disease in infants is in the experience of all clinical physicians of very rare occurrence, or it might be more accurate to say that the disease is but rarely recognized. When it does arise it is usually of an exceedingly mild type; it is apt on occasion to be wanting in essential symptoms, and it may run its course without fever. The danger lies in the fact that unrecognized typhoid fever in infants may be the means of spreading infection. Consequently all doubtful cases should be treated in the same manner as if they were clear cases of typhoid fever.

Zittmann's Treatment of Syphilis.

Lieutenant-Colonel G. H. Sylvester and Captain C. B. Crisp, contribute a paper in the *Journal of the Royal Army Medical Corps* for April, 1905, on this subject, in which they say that the results of this method of treatment, in their experience, has been most satisfactory. The effect is often most marked, and the way a patient who has been going from bad to worse will suddenly improve, both locally and generally, is astonishing. The writers have treated twenty-three patients. Of these, eighteen went through the treatment once; four twice; one three times. In thirteen cases a great deal of good resulted; in two there was some improvement only; in one there was very slight improvement only; in three there was practically no result. The writers conclude that, taken as a whole, the Zittmann treatment seems to have much more effect upon skin and connective-tissue lesions, and in improving the general health and causing increase in weight, than it has in cases in which the chief complaint is of syphilitic pains in the joints.

News of the Week.

A Hospital-Jail for Inebriates.—The Legislature has passed the bill introduced by Magistrate Pool to provide for the establishment in this city of a hospital to which confirmed drunkards or drug habitués may be committed for treatment by City Magistrates or Supreme Court Justices. The hospital is to be under a staff of three physicians appointed by the Mayor. One of the three is to be the chief physician and will receive a salary of $6000 a year. The other two will get $5,000 a year each. The building and its site will be paid for from excise money.

An Organization of Milk Dealers.—Many of the larger milk dealers in the Borough of Manhattan, besides a number in Brooklyn, have just united in an organization, under the title of the "Association for Improvement of the Milk Supply of New York." The object of the movement is expressed in the name of the new organization; but its significance lies in the fact that the principal wholesale and retail dealers in milk have now voluntarily come into cooperation with each other to improve the quality of milk sold in this city. The Association has retained Dr. E. J. Lederle, formerly Commissioner of Health, as consulting sanitarian, adviser, and analyst. The membership includes some forty firms and individuals. The work done by and for the members of the Association includes periodical examination of milk and milk products from the various milk stations and creameries, and of milk from the several farms supplying each station. When these examinations disclose opportunities for improvement in the milk, further inspections are made at the creamery, especially to determine whether the sanitary conditions are as they should be; next, any farmer who may be supplying milk below the creamery standard, will be notified of the fact, and advised regarding methods for improving the product of his farm, with respect both to the richness and to the cleanliness of his milk. They also aim to improve the conditions under which milk is shipped to this city. Some of them are introducing pasteurization as a means to greater cleanliness and better keeping quality of the milk and are inducing those retailers who handle milk in groceries, in the tenement districts, to use better methods in caring for milk while it is in their stores. Another feature of the Association's work will probably be a series of lectures by physicians, sanitarians, and food experts designed to give the wholesale and retail dealer in milk some further knowledge of the scientific side of the business in which he is engaged.

A New Straus Laboratory.—Plans are being prepared for the erection of a new laboratory for the pasteurization of milk for the poor of New York City on the property at 348 and 350 East Thirty-second street purchased for this purpose by Mr. Nathan Straus. The work of dispensing pasteurized milk, which Mr. Straus has carried on for twelve years, has increased to such proportions that the facilities of the present laboratory have become inadequate. In 1892, the year in which the work was started, 34,400 bottles were distributed, and each succeeding year enlarged and widened its scope until

now the demand requires the pasteurization of more than three million bottles a year.

Yellow Fever at Panama.—Three new cases of yellow fever have been reported since April 29, making a total of sixty-one cases since July 1, 1904, with eighteen deaths. Although sanitary conditions are steadily improving, Col. Gorgas, chief sanitary officer, recommends that no more employees be sent to the Isthmus until suitable quarters can be provided for them. Gen. Davis has been recalled on account of malaria which he contracted some time ago, and Col. Gorgas is now acting Governor of the Canal Zone.

Plague in India.—According to *The Lancet,* the official returns show a record of over 53,895 deaths from plague throughout India, during the week ending March 25, an increase of 11,807 over the figures for the preceding week, and this sad showing is termed "a lamentable sequel to the let-alone policy formulated by the Government of India."

Meeting of the Meningitis Commission.—At a recent session of the Meningitis Commission, the definite conclusion was reached that the use of diphtheria antitoxin is without value in the treatment of cerebrospinal meningitis. Fresh air seems to be the greatest desideratum for the patients, and the records of the Health Department show that the severe epidemics of the disease have always come during very cold winters when the houses are shut up tighter than usual. This was true of the years 1872, 1881, 1893 and the past two winters, in all of which years there was much meningitis.

A Meningitis Pavilion at Bellevue.—A special pavilion of thirty-five beds has been opened at Bellevue Hospital for the reception of cerebrospinal meningitis cases sent to the various city hospitals. One object of the change is to afford better opportunities for the study of the disease by the meningitis commission.

Monument to Volunteer Nurses.—A monument to the memory of volunteer army nurses who lost their lives in 1898, has been erected in the National Cemetery at Arlington, and was dedicated last week. The names carved on the monument are those of Miss Minerva Turnbull and Mrs. Isabella R. Bradford of New Orleans; Miss Margaret Greenfield of St. Paul; Miss Katherine Stansbury of Chicago; Miss Ellen May Towers of Detroit, Miss Clara Wood of Rochester, and Miss Irene Toland of St. Louis.

The Osteopathy Bill Vetoed in Pennsylvania.—Governor Pennypacker of Pennsylvania, has declined to sign the bill passed by the last Legislature regulating the practice of osteopathy, licensing those who desired to engage in the practice of this art, and establishing a board of examiners representing the State Osteopathic Association before whom all candidates should appear before they could legally engage in the practice of osteopathy. The Governor's main objection was based on the fact that there was nothing in the bill to indicate what constitutes osteopathy. Approval of the bill would, in the mind of the Governor, appear to give the authority of the State to a system of practice in the healing art that excludes the use of medicine and also surgery. The bill provided that licenses would be issued by the State Board of Osteopathic Examiners and not by the Medical Council of Pennsylvania, and such a course, the Governor held, would be an anomaly in the legislation on the subject.

Gift of a Library.—Dr. Massilon Cassat has presented to the Cincinnati Academy of Medicine a library of three thousand volumes on Medicine and Allied Sciences. He retains a library of four thousand volumes.

New Haven County Medical Society.—It was voted at the annual meeting of this society in New Haven to hold the next meeting in Waterbury in October. The officers are as follows: *President,* Dr. A. A. Crane; *Vice-President,* Dr. R. A. McDonnell; *Clerk,* Dr. William S. Barnes; *Executive Committee,* Dr. Gustavus Eliot and Dr. C. S. Rodman; *Standing Committees—Censors,* Drs. T. J. Eggleston, J. H. Townsend and J. L. Moriarty; *Credentials,* Drs. W. H. Carmalt and E. D. Hall; *Biographical Sketches,* Drs. W. L. Barber and A. E. Winchell; *Public Hygiene,* Drs. F. Bellosa, A. W. Tracey and J. F. Barnett; *County Recorder,* Dr. Caroline North.

The Mississippi Medical and Surgical Association held its fifth annual meeting in Jackson, April 26 and 27, under the presidency of Dr. J. M. May of Westside. The secretary was Dr. H. E. Connor of Brookhaven.

Tolland County (Ct.) Medical Association.—At the one hundred and thirteenth annual meeting of this society held at Rockville, the following officers were elected: *President,* E. O. Winship of Rockville; *Vice-President,* J. B. Stretch of Stafford; *Clerk,* T. F. O'Loughlin of Rockville; *County Reporter,* C. B. Newton.

Texas Medical Association.—The State society wound up its annual session held at Houston by electing the following officers: *President,* Dr. J. E. Gilcrest of Gainesville; *Vice-Presidents,* Dr. M. B. Grace of Seguin, Dr. Thomas A. Rape of Ballinger and Dr. O. I. Holbert of Waco. Fort Worth will be the next meeting place.

Missouri Institute of Homeopathy.—At the recent meeting held in Kansas City, the following officers were chosen: *President,* W. A. Forster, Kansas City; *First Vice-President,* W. E. Riley, Fulton; *Second Vice-President,* J. T. Thacher, Oregon; *General Secretary,* George A. Mellies, St. Louis; *Treasurer,* D. M. Gibson, St. Louis; *Necrologist,* H. W. Westover, St. Joseph.

Mississippi State Medical Association.—Officers for the ensuing year were elected at the recent meeting in Jackson, as follows: *President,* Dr. E. H. Martin; *Vice-Presidents,* Drs. R. A. Seal, W. W. Crawford, and Stephen Eggleston; *Secretary,* Dr. L. T. Fox.

Worcester (Mass.) North Medical Society.—At the annual session held at Fitchburg, the following officers were elected: *President,* G. B. Underwood, Gardner; *Vice-President,* A. P. Mason; *Secretary,* Walter F. Sawyer; *Treasurer,* E. L. Fiske.

Berkshire Medical Society.—The following officers were elected at the annual meeting held at Pittsfield, April 27: *President,* Dr. J. J. Flynn, Pittsfield; *Vice-President,* Dr. A. B. Withington, Pittsfield; *Treasurer,* Dr. W. L. Paddock, Pittsfield; *Librarian,* Dr. W. W. Leavett, Pittsfield.

Hampden District (Mass.) Medical Society.—The annual meeting of the society was held at Springfield, and the following officers elected: *President,* Dr. W. M. E. Mellen, Chicopee; *Vice-President,* Dr. E. H. Guild, Springfield; *Secretary* and *Treasurer,* Dr. F. S. Ward, Springfield.

A Reunion of the Alumni of the College of Physicians and Surgeons, New York, will be held at Sherry's, Fifth avenue and Forty-fourth street, on Wednesday, May 17, at 9 P. M. An address will be given by the Hon. Charles Emory Smith of Philadelphia. Tickets can be obtained from the Registrar of the College on or before Monday, May 15.

Dr. George F. Butler was elected professor of medicine at a recent meeting of the Board of Directors of the Chicago Post-Graduate Medical School.

Dr. Wm. J. Butler has been elected assistant professor of Pediatrics, Rush Medical College, University of Chicago.

Scissors for Cutting Secondary Membranous Cataracts.—In the description of this instrument published in the MEDICAL RECORD of May 6, the reference letter in the illustration places the knife edge, which is ground on the back of the lower blade, in the wrong position. The sharpened edge is but 4 mm. in length and confined to the point of the blade.

Hospital News.—*The Jewish Hospital of St. Louis* now has a fund of $80,000, all contributed by private subscription, for the construction of an annex to the general hospital. When completed the new building will cost about $100,000.

The Willard Parker Hospital.—Plans have been filed with the Bureau of Buildings for the enlargement and remodeling of the main building of the Willard Parker Hospital in Sixteenth street, east of Avenue C. A three-story extension, 38 feet wide and 78 feet long, is to be added on the front and rear, new fireproof staircases are to be built, and a new up-to-date plumbing plant installed. All the new construction work is to be fireproof.

New Beds for Nassau Hospital.—Through the efforts of several well-known persons of Manhattan, sufficient funds will soon be obtained to endow additional beds and possibly enlarge the Nassau Hospital, at Mineola, L. I.

The English Hospital at Nice.—The winter residents of Nice and the Riviera, are very pleased that the troubles in connection with the Queen Victoria Memorial Hospital are now at an end. It was found impossible to finish the building owing to the sudden death of Sir John Blundell Maple, who promised the sum of £30,000 ($150,000), and it is only recently that new friends have come forward with the promise of various sums sufficient in the aggregate to complete the hospital. The subscriptions were headed by Sir George White of Briston, who gave £2,000 conditional upon the necessary amount being raised.

The Sherman Hospital, Elgin, Ill.—The opening ceremonies of the Annex to Sherman Hospital, Elgin, Illinois, were held April 14. The addition nearly doubles the capacity of the institution, which will now accommodate 52 patients. The new building was erected at a cost of about $33,000.

New Hospitals in Chicago.—Plans have been prepared for the erection of the Swedish-American Hospital at Green and Sixtieth streets, Chicago, at a cost of $100,000. Isaac Greensfelder, who a quarter of a century ago turned the first spadeful of earth in the excavation of the Michael Reese Hospital, recently performed the same office for the erection of the new hospital, which will cost $475,000.

Illinois State Hospitals.—The Illinois Legislature has appropriated $380,600 for the maintenance of the Illinois Western Hospital for the Insane, at Watertown, for the next biennium. The appropriation for the Illinois Eastern Hospital for the Insane, Kankakee, was reduced to $154,000.

German Hospital of Chicago.—At a recent meeting of the Board of Directors of this institution, the following appointments were made: Consulting physician, Dr. Julius H. Hoelscher; attending physicians, Drs. Rudolph Menn and Frank W. Lambden; attending surgeons, Drs. Wm. C. Wermuth and Emanuel J. Senn; attending gynecologists, Drs. H. Edward Sauer and Cecil von Bachelle; attending oculist and aurist, Dr. David Fiske; attending obstetrician, Dr. W. F. Grosvenor, and skin and genito-urinary diseases, Dr. Louis E. Schmidt.

Obituary Notes.—DR. JOHN HOWARD PUGH died at Burlington, N. J., on May 1, at the age of seventy-eight years. He was born in Chester County, Pa., and was graduated from the medical department of the University of Pennsylvania in the class of 1852. He entered upon the practice of his profession at Bristol, Pa., but in 1854 he removed to Burlington, where he continued to live. During the Civil War he served without pay on the corps of physicians at the United States General Hospital at Beverly. He served a term of two years in Congress, and was at one time a member of Common Council and of the State Board of Education. He was president of the Burlington Library Association and of the Burlington County Medical Society.

Dr. HENRY H. PARROTT, the first physician to settle in Douglas, Wis., died in that town on April 18, at the age of eighty-five years. He was born in England, and was a licentiate of the Royal College of Surgeons, London, in 1842. He had practised in Douglas for 55 years.

Dr. G. LEWIS YAGER, died at Dorchester, Mass., on April 13, at the age of twenty-nine years. He was born in Chester, Pa. He was a graduate of Howard Medical School in 1901.

Dr. HENRY UTLEY of Sterling, Ill., died on April 27, at the age of eighty-three years. He was a graduate of the New York University Medical College in the class of 1849. He was a surgeon in the Seventy-fifth Regiment of Illinois Volunteers during the Civil War, and when compelled to leave the service; on account of a severe wound, in 1863, he settled in Sterling.

Dr. WILLIAM L. BAIRD of Jackson, Tenn., died on April 24, at the age of sixty-six years. He was a graduate of the Medical Department of the University of Louisville, in the class of 1885.

Dr. WILLIAM CUMMINGS SHANNON major and surgeon, United States army, died April 21, at Elkhorn, Nebraska. He was born in 1851 in New Hampshire and was a son of Dr. Nathaniel Shannon, who lived and practiced medicine for many years in Maine. He graduated from Westbrook Seminary in 1868 and from Bowdoin College in 1872 and received his medical degree from the Bellevue Hospital Medical College in 1875, receiving his commission as assistant surgeon, U. S. A., the same year. He was retired on account of illness in 1898.

Dr. WILLIAM B. WARREN of Groton, Mass., died of apoplexy on April 29, at the age of fifty-one years. He had practised in Groton since 1883.

DR. WILLIAM M. EDWARDS, superintendent of the Michigan Asylum for the Insane at Kalamazoo, died on April 26. He was born near Peru, Ind., in 1856, and was graduated from the medical department of the University of Michigan in the class of 1884, receiving his appointment to the staff of the asylum before graduation. He succeeded Dr. George C. Palmer as superintendent in 1891.

Dr. GEORGE HENRY of Denver, Colo., died suddenly on April 23, of disease of the heart following an attack of influenza. He was born in Poland, and was graduated from the Long Island College Hospital, Brooklyn, in the class of 1860. He had lived in Denver about 20 years.

Dr. WILLIAM C. RAVENEL of Charleston, S. C., died on April 21, at the age of seventy-six years. He was a graduate of the Medical College of the State of South Carolina, in the class of 1850. He retired from the practice of medicine a few years ago and went to live in Baltimore.

Dr. ISAAC NEWTON GARD of Greenville, Ohio, died on April 24. He was born in Butler County, Ohio, in 1811, and was graduated from the Miami Medical College, Cincinnati, in 1834. He organized the Darke County Medical Society and was its

president for many years. He retired from active practice about twenty years ago.

Dr. Leonidas S. Burchard of Oakland, Cal., died on April 23, from pneumonia at the age of fifty-three years. He was a graduate of the Medical Department of the University of California in the class of 1882.

Dr. J. J. Giltenan of Chicago, died at the Alexian Brothers' Hospital, after an illness of several weeks, on April 24. He was sixty-two years old, and was an inspector of the Chicago Board of Health.

Dr. Seymour C. Troutman died at his home in Somerville, N. J., on May 6, at the age of eighty-three years. He was born in Brooklyn and was graduated in arts from Columbia College in 1843. He established a drug business in Brooklyn, but later studied medicine and was graduated from the College of Physicians and Surgeons in 1854.

Obituary.

ALBERT A. DAVIS, M.D.

NEW YORK.

Dr. Albert A. Davis died at St. Luke's Hospital in this city, on Saturday, May 6, in the sixty-eighth year of his age, of progressive muscular atrophy. He was born in Danville, Vt., and was graduated from the College of Physicians and Surgeons, New York, in the class of 1864. While still a student he served on the medical staff of one of the public institutions of the city, and from there went, in 1863, to St. Luke's Hospital, as assistant house physician. After graduation he served for a time in the army hospital at Willet's Point, and later reentered St. Luke's as house physician. From that time until his death he was continuously connected in one capacity or another with this institution. After having served a long time as interne he became examining physician for the hospital, and later was appointed on the attending staff. When stricken with his final illness and compelled by increasing infirmity to resign, he was immediately appointed consulting physician by the Trustees in recognition of his long and faithful service to the instituton.

Dr. Davis was of the old order of medical men, thoroughly versed in the practical side of medicine, an acute diagnostician and a careful and successful therapeutist, but of a retiring disposition and constitutionally incapable of pushing himself forward into the place in the medical world, which his abilities would have entitled him to fill. He was a plain man, sprung from the ranks of the plain people, retaining to his last day the quaint accent of the New England farmer—but also a man of learning and culture, a lover of good books and pictures, and in a modest way a discriminating collector of both. He thought naught but good of his fellows and his life was filled with kindly acts and helpful counsel to the younger men of the profession, especially those with whom he came in contact in his hospital work. To the poor also he gave of his time and his medical advice freely, and his reward was in their loving gratitude. The esteem in which he was held by his colleagues was expressed in a paper, signed by every member of the attending and consulting staff of St. Luke's Hospital, voicing their sympathy with him in his affliction and the sorrow they felt in losing him as a colleague. His last days were brightened by this touching tribute of affection, for kindliness was the keynote of his nature, and the love of his fellows was more to him than fame or riches. That which he so prized he received in full measure.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PRESIDENT R. C. P.—SANATORIUM TREATMENT—HOSPITAL APPEALS AND MEDICAL COMPETITION—THE KING'S FUND AND THE JUBILEE HOSPITAL TROUBLES—ACTINOMYCOSIS OF THE GALL-BLADDER — JEJUNOSTOMY—CHOLEDOCHOTOMY—CORPUS LUTEUM.

London, April 21, 1905.

Sir Richard Douglas Powell, Baronet, K.C.V.O., M.D., etc., was on Monday elected President of the Royal College of Physicians, in succession to Sir William Selby Church, who has held the office for the unusually long period of six years. The new president became a member of the college in 1867, was elected a Fellow in 1873 and appointed senior censor in 1902. He is physician extraordinary to the King, having been physician in ordinary to Queen Victoria. He is consulting physician to the Middlesex and Consumption Hospitals, and this year president of the Medico-Chirurgical Society. His valuable contributions to diseases of the chest from 1872 onwards are well known to you. The election has given general satisfaction.

On Saturday the chairman of the Metropolitan Asylums Board received a rather influential deputation representing medical officers of health and those specially interested in the prevention of consumption. The object was to induce the board to undertake the duties of a sanatorium authority for London. Dr. Orme Dudfield said he estimated provision for 2,000 beds would suffice to accommodate 4,000 patients per annum at a cost of only £130,000. The secretaries of the hospital Sunday and Saturday Funds spoke in support of the movement.

The chairman of the board was quite sympathetic, but he very naturally doubted whether the ratepayers generally were prepared to incur the expense, as they were scarcely educated on the question. His board in 1903 threw on the local government board the burden of advising in the matter. The whole subject was afterwards referred to the general purposes committee for consideration to report.

The question of the ratepayers' willingness may well cause hesitation. The extravagance of the Asylums Board and the County Council has given rise to much discontent. In some districts the rates have been raised to 10 and 12 shillings in the pound, and there are indications that the long-suffering payers may awake from their apathy and put an end to municipal speculations, and possibly to beneficial institutions.

Hospital appeals for funds increase at an alarming pace. Extensions, rebuildings, enlargements, new departures, are all pleaded, until there is a fear among some that the available fund of charity may be exhausted. The governors of St. George's Hospital have decided to ask for £350,000 for the purpose of rebuilding their institution, which is not quite so up to date as some of the newer or more recently renovated hospitals. But excellent work has been carried on in St. George's up to the present time, and it would be well worth considering whether something less than rebuilding would not suffice for another generation.

Guy's Hospital is again in the field with a large demand. It is but a few years since a huge sum was subscribed by the public, and since then new buildings for nurses and other things have also been appealed for and liberal responses given. Guy's also possesses a noble endowment, but with all seems unable to make ends meet. The new demand is for £100,000, and the appeal is being well engineered. It may be as well perhaps to ask the governors for a more detailed defence of their stewardship. The profession has never been slow to admire the noble work of Guy's, but some of its later doings have produced no little dissatisfaction. Its out-patient department requires overhauling—not in the sense the managers might use the term—but with a view of ascertaining how far it is conducted in a spirit of right—economical and moral. Guy's, like the London, takes pence from its out-patients, nominally for the medicine, but the poor people cannot be expected to draw fine distinctions between advice and medicines, or between selling and partially giving, one or the other. The very fact of paying, however small the sum, gives a different meaning to the transaction, and we already hear many people talking of their rights in hospitals or comparing the prices paid to them and to practitioners. The competition in the profession and the poverty of large sections of the public has reduced the remuneration of medical services to the lowest point, and in some of the poorer districts it is impossible for a doctor to earn a living.

Yet here is a great hospital, richly endowed and with a great subscription list, offering advice and medicine for 2d. or 3d. Either the patients thus brought into its out-department are able to pay the local practitioner or are proper persons for poor law relief. Guy's should spend its income on real charity, maintaining its in-patient department. To sell medicine at prices the poorest pharmacist cannot af-

ford and to throw medical advice into the bargain is degrading its position and its staff, as well as injuring the struggling practitioner. Hospital consultants have never made a stand against this system and may be charged with being parties to it. But when they have ruined their chief supporters, the general practitioners, they may find they have set up more powerful competitors in hospital managers. Already Guy's has wards for pay patients, and those who enter them are withdrawn from the practice of both general and consulting practitioners. More than this, Guy's has set up an electrical department, where paying patients are treated, thus competing with the specialists.

It seems to me a very doubtful point whether a hospital can legally divert trust money given to the poor to such a purpose, and I should like to see the question brought before the courts. I have dealt only with Guy's because the moment of a new appeal is opportune, but you must not suppose that this is the only hospital where such things are being done. The matter is growing more and more urgent.

The troubles of the Queen's Jubilee Hospital are by no means ended. It has never been considered necessary and has never had the confidence of the profession. Its managers having appealed to the King's Fund to inquire into the recent scandal, Mr. F. M. Fry and J. D. Power undertook the investigation. They held three sittings, examined twenty-three witnesses, inspected the house and have made their report. This document is remarkable, if not unique, and illustrates the tendency of committees and arbitrators to compromise matters. The investigators did not confine themselves to the recent troubles. They went back to the founding of the institution by a general practitioner, who claims to have spent a considerable sum upon it and has been a manager and surgeon to it. On this the inquirers say it was reasonable he should have a seat on the board, but not be on the staff, as he was only a member, not a Fellow of the College of Surgeons—a view which will not obtain general acceptance. That these gentlemen are unable to appreciate the relation of various diplomas is shown by the statement that surgeons of hospitals should "at least" be Fellows, although that is the highest grade in the college. They go on to say that after the resignation of a hospital staff an independent inquiry should be made before appointing a new one, and so complicating the matter by the existence of a third body. Then they condemn the management as "slack and unsatisfactory," say the old staff had not a free hand, and the new staff is increased in size, and now numbers more persons than there are beds in the hospital. Further, they conclude that a hospital for in-patients is not required on the spot, but if a new building were erected it might serve as a casualty and out-patient department. Now comes the most amazing part of this extraordinary report. It is proposed that both the new staff and the managers resign—that for twelve months a sort of interregnum shall exist, a small committee appointed by the King's Fund to act *pro tem.* in conjunction with the presidents of the two Royal Colleges, and at the end of the period the governors to resume and frame a reformed constitution. But they do not see how this can be done unless the King's Fund will find £1,000 to start the new board. Thus having shown that the hospital is not required, instead of recommending its abolition, they would patch it up and ask the Fund to give money to build an out-patient dispensary within a short distance of the Chelsea dispensary, which has been obliged to transform itself into a provident institution in order to maintain itself. And this complex proposal to carry on and to waste money, instead of saying what they evidently think, that the hospital ought never to have been established and should be forthwith abolished.

Mr. Mayo Robson had practically the whole meeting of the Medico-Chi. (on the 11th) to himself, and right good use he made of it, his communications being on those points of advanced surgery of which he is so experienced and able an exponent. He read a full account of a case of actinomycosis of the gall-bladder, which may, I think, be said to be the only one met with, though of course there is no reason why the disease should not attack the gall-bladder as well as other abdominal viscera. The patient was a man of 47, who had been out of health for eighteen months, but for the last three had suffered acutely from abdominal pains and constant aching. A tumor was found beneath the right costal cartilage, which extended below the level of the umbilicus. Cholecystitis was diagnosed and an operation performed. Iodide was given, and the man was quite well three years later.

Another case related by Mr. Robson was one of adenoma of the gall-bladder—a rare condition, also somewhat of a pathological curiosity, only two such cases having been recorded. The point in this case was that the tumor produced symptoms exactly like those of gall-stones, for which the patient had been treated without relief. On opening the abdomen, the condition was made out, and cholecystectomy performed. The patient lost all pain and went home at the end of the third week.

Mr. Robson then described a new method of jejunostomy proposed for such extensive cancer of the stomach that gastrotomy or other operation was unavailable.

Finally Mr. Robson read a paper on 123 cases of choledochotomy. Referring to his paper in the *Transactions* for 1902 on calculi in the common duct, he said when choledochotomy was first employed the mortality was 16.2 per cent. Since adopting the method for complete exposure of the bile passages a continuous series of seventy-six operations had resulted in a mortality of 3.9 per cent. In several cases he found calculi in the common duct when there was no jaundice, and but for careful examination the patient would not have been relieved. As operation was the only resource, every recovery was a life saved.

In reply to some questions put to him, Mr. Robson said he thought the reason why jaundice was absent in some cases probably was that the duct in them was not completely occluded. The most unusual feature in the cases was absence of pain. He thought from two to three inches of the surface of the liver should be used in forming an anastomosis. He had never removed the capsule of the liver, but he had that of the kidney.

The Corpus Luteum was discussed lately at the Obstetrical Society, when Dr. C. Lockyer gave a lantern demonstration on its development and retrogression, with special reference to the compound lutein cystomata found in association with vesicular mole and chorioepithelioma. Dr. Williamson did not believe lutein cells migrated from distant corpora lutea: they arose *in situ*. The pigment was a lipochrome.

Dr. Blacker said the corpus luteum was in fashion just now. It was by no means certain that excess of lutein bore any relation to vesicular mole or chorioepithelioma. Seitz had found excess in thirty-six ovaries at different stages of pregnancy. If further observations showed such excess in all normal pregnancies its presence in other cases would only be a coincidence.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

A GENERAL HOSPITAL IN MANILA—SMALLPOX IN THE ISLANDS AND ON WARSHIPS—PERSONAL NOTES.

MANILA, P. I., March 17, 1905.

THE question of providing a proper general hospital in the city of Manila is one that has given the authorities considerable cause for thought. The Commissioner of Public Health has been most active in advocating its establishment. The buildings of the present Civil Hospital, which is maintained by the Insular Government, are most unsatisfactory. Efforts have been made from time to time to induce the Philippine Commission to make an appropriation to defray the cost of constructing suitable buildings, but the reply has always been made that the condition of the treasury would not warrant such a step. For a time it seemed that this highly desirable undertaking might be accomplished by private parties. Bishop Brent, of the Episcopal Church, thought that the necessary funds could be collected in the United States. The principal drawback to such a scheme is to obtain the necessary money to cover the current expenses after the hospital is built. It was thought that the commission would consent to make appropriations for the operation and maintenance of such an institution, but no positive assurance could be had. Unless this condition could be met and the future provided for it would be worse than useless to erect the buildings.

The medical men of the Philippines cannot hope to make much progress toward treating tropical diseases successfully unless proper hospital facilities, where accurate observations can be made, are provided. The layman in Manila, not in the military service, finds it most difficult to obtain admission to a hospital because of the small number of beds, and these are always occupied. The laymen in the provinces is generally even much worse off, because there are not only no hospitals in the provinces, but no medical men. Upon being stricken down with disease the resident of the provinces is compelled to come to Manila for relief and upon arriving here he often finds that the hospitals are filled. The Insular Government hopes to ameliorate this condition of affairs very shortly, at least to a limited extent. The hospital now occupied by the army, usually known as the First Reserve Hospital, is to be vacated in the near future. The army expects to move into its new buildings at Fort William McKinley. By making some repairs and alterations it is hoped that at least two hundred patients may be cared for in the buildings about to be vacated by the army. The structures are not ideal by any means, but they are so far superior to the ones occupied at present by the Civil Hospital that comparison is scarcely necessary.

Smallpox still continues to make its appearance at various points throughout the islands. The vaccinating parties sent to such places usually succeed in stamping out the

disease. It has been reported recently that in one of the churches of the northern provinces the virgin would cure all cases of smallpox and confer immunity upon all the faithful who would come there to worship. Persons suffering with the disease have begun to assemble at the church, and they are accompanied by many others who wish to see the cure or who expect to receive the immunity themselves. The Provincial Board of Health has ordered the church to be closed, but it is understood that the church authorities have objected to this order upon the ground that the health officer who issued the same belonged to another religious sect, and was therefore prejudiced. The Insular Board of Health has decided to meet the situation by sending vaccinators to the church with instructions to inoculate everybody. This will probably have the effect of stamping out the disease, and the result will be variously credited to science and to religion according to the point of view.

Smallpox has broken out a number of times recently among the crew of the battleship Wisconsin. Upon the appearance of the last outbreak the ship was turned over to the United States quarantine authorities, and they remanded the vessel to the Mariveles Quarantine Station for thorough disinfection and the vaccination of the entire personnel. Sixteen days have elapsed since that was done and no further cases have made their appearance, and it may therefore be assumed safely that the disease has been stamped out.

Dr. H. B. Wilkinson, the physician in charge of the San Lazaro Hospitals, has gone to the United States on a four months' leave of absence.

Major Banister, United States Army, the surgeon in charge of the First Reserve Hospital during the past two years, has completed his tour of duty in the Philippines and has been relieved by Major Fitzhugh Carter, United States Army, and has returned to the United States on the transport Sherman.

Major H. I. Raymond, United States Army, the officer in charge of the Medical Supply Depot, has completed his tour of duty in the Philippines and has been relieved by Col. D. M. Appel, United States Army, and has returned to the States on the transport Sherman.

Captain and Assistant Surgeon Hess, United States Army, who has been on duty at the Cuartel de España, has left on a two months' leave of absence in China and Japan.

CEREBROSPINAL MENINGITIS AND THE DISTRIBUTION OF THE BLOOD.

To the Editor of the Medical Record:

Sir: I was very much interested in the communication of Dr. Goodall of Bennington, Vermont, on bleeding in cerebrospinal meningitis. The success of his method has two significances to my mind: Firstly, the release of pressure from the cranial space and spinal canal, and the relation of these pressures to the distribution of the blood. In regard to the first consideration, the evidence is daily accumulating that cerebrospinal pressure bears a very intimate relation to the distribution of the blood, *i. e.* when the circulation is deflected to the cerebrospinal centers, cerebrospinal pressure is the consequence, and conversely when determined from these centers to the periphery, the pressure is relatively reduced.

The recent reports of brilliant results following the equalization of the blood by hypodermically administered ergot, after the method of Dr. Alfred T. Livingston, certainly parallel the cases of Dr. Goodall, and moreover substantiate the analysis of therapeutic action as above given.

Dr. Goodall's additional measure of "steaming" the periphery, is a valuable accessory means of attaining the same end, namely the determination of the blood volume to the periphery, thus relieving cerebrospinal congestion and consequent stasis.

I think few indeed of Dr. Goodall's readers will agree with him that there is any superabundance of blood in the bodies of patients suffering with cerebrospinal meningitis, any more than any other disease, or in fact that bloodletting is other than harmful, except for the relief given to the cerebrospinal pressures, and this as we have seen above is obtainable by other measures, more humane, just as effective, if not more so, and with perfect freedom from untoward effects.

I agree with Dr. Goodall that it is far preferable for physicians, not amply prepared for cerebrospinal puncture, to resort to measures of relief of the nature of his steaming bath, and also to give ergot by Livingston's method, though it must be understood in advance that ergot internally administered is a failure.

Homer Wakefield, M.D.

New York.

Progress of Medical Science.

Boston Medical and Surgical Journal, May 4, 1905.

Subacute Perforation of the Stomach.—The histories of three cases are given by F. B. Lund, who refers particularly to those conditions in which a very small opening may become plugged by a bit of omentum or by fibrin. In such a case the perforation becomes almost at once walled off by adhesions from the general peritoneal cavity. The general ideas the author advances are summarized in the following propositions: (1) The symptoms of subacute perforation of the stomach are similar to those of acute perforation, with the important exception that they are less violent and are not followed by collapse or by the development of general peritonitis. (2) The location of the pain and tenderness depends upon the location of the ulcer and varies with it. (3) The treatment should be, if possible, posterior gastroenterostomy without breaking up the protective adhesions.

Certain Aspects of the Differential Diagnosis between Epilepsy and Hysteria.—J. J. Putnam and G. A. Waterman gives the histories of eleven cases, illustrative of the difficulty of diagnosis between the two conditions named. They realize the difficulty of the situation, especially in dispensary practice, where the patient is seen only at intervals, and where the testimony of friends is so unreliable. They, therefore, suggest that every neurological staff should contain a man skilled in psychopathical research who should review from time to time all doubtful cases. While they are disposed to admit that the diagnosis of so-called idiopathic epilepsy is considerably more brave than that of hysteria, and that these two affections represent different tendencies, they declare that such a statement needs some qualification. It is probable that the term epileptic, as implying a tendency to outbreaks of certain sorts, covers a variety of pathological tendencies, and the mere form of the attack does not always enable us to distinguish between them. Thus, epileptic fits as seen in cases of brain tumor may be indistinguishable in themselves from those met with in cases exhibiting the familiar degenerative tendency associated with the name of epilepsy in general. Again, degeneracy itself is by no means always present in epileptic conditions, even those classified as idiopathic. Too little is known of the physiology of the epileptic seizure, in its varied forms to enable one to say there is a sharp distinction to be drawn between such an attack as occuring in hysteria and another which might be found in epilepsy proper. However much it may be believed that these two forms are different, it is impossible at present to give the ground for such belief.

New York Medical Journal, May 6, 1905.

Adenoids in the Adult.—D. M. Barstow finds from a study of the subject that adenoid growths in the adult are more common than is generally supposed. This lesion is a frequent cause of nasopharyngeal catarrh with its annoying postnasal dropping. It may cause nasal obstruction and apparent hypertrophic rhinitis. The study of the cases narrated by Barstow shows that this condition should always be suspected in ear disease and pulmonary tuberculosis.

Politicosociological Aspects of Tuberculosis Problems.—Jonathan Wright notes the changing view with reference to the real underlying cause of tuberculosis. We have turned from the extreme ideas of Koch in regard to the relative importance of the bacillary factor to the conviction that the question of strengthening the resisting power of the cells of the human body is by far the most important phase of the whole matter. Tuberculosis is not to be classed in the same grade of contagion with cholera. The bacillus is a "thick-hulled" organism and comparatively easily thrown off by healthy tissues. The whole matter turns on the possibility of providing proper housing, food, and exercise for the multitudes. It is by progress along these lines that the mortality rate of tuberculous diseases has fallen and not by any distinctively medical measures as such. Progress in this direction began long before the modern conception of the communicability of the disease. So far as figures show, there has been less improvement in mortality statistics in the years since special measures against the bacillus have been in force than in the corresponding preceding period.

Medical News, May 6, 1905.

Treatment of Non-Malignant Diseases by the Röntgen Ray.—R. H. Boggs presents the following conclusions: (1) It is necessary to distinguish between the non-malignant diseases which should, and those which should not be treated by the *x*-ray. (2) While the continual cry of technic may become tiresome to some who think the subject can be mastered in a few days or a couple of months, the method of application of the rays and the judgment of the operator accounts largely for successful or unsuc-

cessful work. (3) It is just as essential to administer a therapeutic dose when applying the Röntgen rays as it is when prescribing powerful drugs. (4) Idiosyncrasy is not a frequent cause of excessive dermatitis. (5) A dosage which causes stimulation of healthy tissues will usually produce a slight reaction in diseased tissue. (6) At all times, it should be remembered that it is not so much the *x*-ray that cures as the judgment with which it is employed. (7) The *x*-ray is one of the best therapeutic agents known for the treatment of acne and many other skin diseases, but it is unnecessary in many instances to treat the trivial and less obstinate cases by this method. (8) The *x*-ray, supplemented by Finsen light, is the most efficient therapeutic agent for the treatment of lupus. (9) The *x*-ray is the most efficient agent for the treatment of certain tuberculous glands, Hodgkin's disease, and selected cases of goiter.

Nasal Conditions Dependent Upon the Generative Organs.—J. Sinexon draws attention to the following facts: During coitus there is always a turgescence and hyperesthesia of the nasal mucosa. In women there is a more or less marked periodical engorgement of the nasal tissues coincident with menstruation and it also occurs periodically during pregnancy. Operations destroying the functions of the generative organs cause the nares to revert to the state existing prior to puberty. In the lower animals sexual excitement is always accompanied by nasal occlusions. In the human species, nose bleed or hydrorrhea may result from the same cause. The result of over-stimulation of the nasal mucosa from sexual perversion may lead to permanent relaxation through vasomotor paresis.

American Medicine, May 6, 1905.

Adulterations of Drugs.—H. W. Wiley says the extent of drug adulterations is probably much greater than is commonly supposed. The fact that properly written prescriptions may result in a concoction of a remedy much different from that required is a matter that cannot be ignored. According to Dr. Wiley these adulterations consist of (1) substitution, *i.e.* providing an article entirely different from the one prescribed or an article which may resemble the one called for in many of its physical, chemical, and therapeutic properties. (2) The degradation of the drug by adding an inert material or extracting a valuable one so that its properties are impaired. (3) Drugs which are "misbranded." These are sold directly to the consumer, without passing under the inspection of the physician. In order to combat the prevailing suspicion concerning drug adulterations, every pharmacist should be taught the necessity of honor and honesty in his dealings and be advised to buy and sell only pure and unadulterated materials.

New Operation for the Relief of Flat-Foot.—Wilson and Patterson present a favorable report of a new operation for flat-foot, consisting of an arthrodesis of the astragaloscaphoid joint and the transplantation of the tendon of the extensor proprius hallucis, through a hole drilled in the scaphoid bone, an adaptation of Wolf's operation for paralytic valgus. The loss of function of the transplanted extensor of the great toe is but temporary and until the extensor brevis digitorum becomes educated to overcome the toe-drop. The after treatment is fully as important as the operative correction and consists of well-adapted physical culture drills. This procedure has yielded better functional results than is possible by the use of arthrodesis alone. The combined operation for flat-foot now described, for the first time, offers no serious difficulties, the additional damage to the structures of the foot necessitated by this procedure is inconsiderable, the time required for treatment not longer, and the results obtained more certain and satisfactory. It would, therefore, seem well to adopt the combined operation in all suitable cases.

Diet in Typhoid Fever.—J. B. Nichols advocates a more liberal and more varied diet in typhoid fever than is now customary. He is opposed to the exclusive liquid diet so-called, arguing that liquid foods are not necessarily more digestible or less irritating to the bowel than are solid foods. He believes the consistency and condition of the food in the intestine is a criterion of more importance than the fluidity or solidity of the food before ingestion. Nichols gives the published results obtained from mixed and liberal feeding in typhoid fever, covering a total of 1,000 cases, with 77 deaths. This low mortality of 7.7 per cent. does not bear out the common apprehensions as to the dangers of departure from milk diet. Complications were not increased by the free diet. The patients were markedly more comfortable and contented, their strength appeared better maintained, convalescence was materially shortened, and from the improved resistant power the mortality rates appeared appreciably lowered, comparative statistics showing an improvement in the death rate of from 2 per cent. to 4 per cent.

Benign Strictures of the Esophagus.—C. D. Spivak divides benign stricture of the esophagus into (1) congenital and (2) acquired. Acquired stricture may be divided into: 1. Organic: (a) after ingestion of corrosive substances; (b) after the healing of an esophageal ulcer; and (c) lues, 2. Mechanical; (a) presence of foreign bodies; (b) polypi, and (c) thrush. Due to compression from without, as tumors, enlarged lymphatic glands, aneurism of the aorta, periesophageal abscess; and verticulum of esophagus filled with food. 3. Spasmodic. The majority of all cases of benign stricture are due to cicatricial obliteration, the result of losses of substance following scalds, produced by caustic substances. Spivak says the symptom, epecially referable to deglutition, are, (1) a short period at the beginning when swallowing is impossible—the period of esophagitis—followed by (2) a period lasting several months, when deglutition is not impeded, and (3) a period when the difficulty to swallowing gradually redevelops—the period of stenosis. During the inflammatory period he advises rest, alkalies in acid poisoning, and vice versa, ice to the sternum, stimulants. Gradual dilatation should be employed early. Conic semisolid elastic esophageal bougies should be used. Metallic or whalebone sounds with olive tips should be avoided. The bougie should be left in the esophagus for several minutes. At first the sound should be passed every day, and later every other, or third day. When dilatation is complete, a bougie should still be passed at intervals of one month to prevent relapse. He reports three cases.

The Gynecologist and the General Surgeon: Their Respective Fields.—Brooks H. Wells says there is necessity for the special study of gynecology. It is a broad and important portion of medicine, not by any means all surgical, and necessitating a highly trained judgment, extensive clinical experience and skill in its details of etiology, diagnosis, prognosis and treatment. While theoretically limited to the pelvis, gynecology must practically include the surgery of the abdomen in women. This work can be best done by the trained abdominal or gynecologic surgeon. Wells protests against the recent and increasing tendency for the amateur gynecologist or surgeon, and physicians in general, with little or none of the necessary surgical experience, skill in diagnosis or appreciation of danger, undertaking with a blind confidence the most complicated and serious abdominal or pelvic operations.

Journal of the American Medical Association, May 6, 1905.

The Curability of Early Paresis.—C. L. Dana suggests that paresis, like tabes—with which it is closely related as a parasyphilitic disorder—may be arrested in its earlier stages. By "arrested" he does not mean the well-known remissions of the disease; in these, he says, there still remains a certain amount of paretic mental impairment, but he rather means a complete disappearance of all evidence of degenerative changes in the brain. He reports a number of cases illustrating his contention, in which symptoms decidedly indicative of paresis appeared, characteristic mental changes, convulsions, Argyll-Robertson pupil, etc., but which disappeared under treatment, and the patients remained well for various periods under observation. The treatment generally consisted in complete change of life, antisyphilitic medication, preferably hypodermic, hydrotherapy, and attention to the general nutrition. He says there is no *a priori* reason why paresis in its early stages may not be sometimes cured, and he holds that the cases he here reports point that way and indicate the importance of an early diagnosis and treatment of this disorder which has been heretofore considered incurable.

X-Ray Treatment of Cancer.—The microscopic changes in the tissue, says E. G. Williams, should be our guide as to the therapeutic possibilities in the *x*-ray treatment of malignant growths. It is evident, he states, that the elements of the tissue are affected according to their vitality. Dead organic matter is unaffected, and the more active the growth the greater the effect. Next to this is the accessibility of the tissues to the rays. Hence the better results with superficial or skin cancers. That moderately deep tissues can be affected is shown by experience, and the way to reach them without producing necrosis of overlying tissues is to lengthen the distance of the tube and the time of exposure. For deep growths, radical surgical measures should be recommended, as the patient should be given the benefit of the probability rather than the possibility of good results. In such cases, however, operation might be rationally followed by *x*-ray treatment to destroy what may remain of the malignant growth. Inoperable cases should be treated by the *x*-ray because remarkable results have been obtained and the most distressing symptom of pain relieved.

Protection from Röntgen-Ray Injuries.—C. L. Leonard calls attention to the serious risk that *x*-ray operators undergo, especially if they follow the practice advised of testing the qualities of the rays on their hands with the fluorescent screen. The only practical method is to limit their radiated field by covering the Crookes tube. For this purpose he uses a pasteboard box a little wider than the diameter of the tube and covered with *x*-ray lead foil a little heavier than the ordinary tea lead. This extends two

inches below the bottom of the box, and can be adjusted so as to limit the field to any extent required. It is not necessary to cover the anode end, and the box is held on a bracket over the portion of the body to be treated; if a very small field is required, a local shield may also be employed. He thinks possibly some effects are due to the strong induction field surrounding the coil which, especially in large hospitals, should be kept in another room, but with the controlling apparatus within the operator's reach. For the dermatitis of the operator's hands, he advises, twice daily soaking in very warm water and scrubbing with Eichhoff's superfatted resorcin soap, followed by inunction of lanolin containing half an ounce of boric acid and a dram of resorcin to the ounce. For the acute erythema of *x*-ray treatment, he employs a stearate of zinc powder with 10 per cent. ichthyol, which he thinks acts as a prophylactic against severe burns. This should not be confused with stearate of zinc ointment, which may do harm.

Eyestrain.—A. G. Pohlman takes up the subject of the etiology of eyestrain from a phylogenetic point of view, and assumes that the abnormalities of human vision are due to the change from the aboriginal to a domesticated condition. In this he includes, however, the changes from a horizontal position of the spinal axis to the upright position, and the more anterior and parallel position of the eyes, etc., which are shared by the higher simians with mankind. In man, however, there is a still further extension of the process, and there is developed a power of sustained convergence for nearwork. The divergent tendency exists in all animals, as is evident during sleep and after death. The special headache of sightseers is not due to strain on the elevator muscle, but to that on the internal rectus to overcome the greater divergence caused by looking upward. The tendency of civilized man is toward myopia, and the failure of sight in old age is a reversion toward the animal normal.

The Lancet, April 29, 1905.

On the Absence of Marked Diminution of Free Hydrochloric Acid in the Gastric Contents, in Malignant Disease of Organs Other than the Stomach.—In a series of cases observed by W. Alexander, R. E. Kelly and H. E. Roaf, the amount of free HCl present in the stomach contents was determined in seventeen instances of malignant disease of the uterus, mamma, rectum, tongue, cheek, etc. In about two-thirds of the cases the free HCl was found to be entirely absent, while in the remaining cases the amount was much below the normal. The authors postulate the fact that the absence of free HCl in cancer of the stomach is not due to local action in that organ, but that it is absent or greatly reduced no matter what may be the situation of the malignant process. This result is to be ascribed according to the authors to a diminished concentration of the hydrogen ions in the blood plasma, but we have no means at our command, so far as we know, to prevent this diminution.

Latent Pneumothorax.—B. C. Stevens declares that in addition to those cases of pneumothorax due to phthisis and trauma, there are other cases in asthmatic subjects with emphyema in which one of the distended air vesicles on the surface of the lung may attenuate its pleural covering and this condition plus some slight extra strain may cause the vesicle to burst and allow eau to enter the pleural cavity. He has observed in the post-mortem room such unruptured vesicles, one being as large as a hen's egg. He records the history of a clergyman, who was suddenly attacked by a pain around the heart. When seen by the author twenty-four hours later he had considerable dyspnea, but was not cyanosed, and the left chest presented the classical signs of pneumothorax. Under a sedative régime a normal condition of affairs gradually returned, and in three weeks he was well. The author explains the case as follows: The patient was an asthmatic. As a curate he had been taught to use the lower part of his lungs in phonation so as to save his larynx. This had no doubt been an extra strain on his already over-distended lungs. The treatment in such cases is the expectant one. Put the patient under the best hygienic surroundings, give alcohol, if there is distress; the nutriment must be easily assimilable and not such as might give rise to flatulent dyspepsia. Of drugs iodide and arsenic are useful at first, and some petroleum emulsion later.

A Case of Extensive Cutaneous Diphtheria with an Examination of the Nervous System.—C. Bolton and D. Brewer discuss the question of systemic poisoning from cutaneous diphtheria, and describe the case of a female child eighteen months old, who had a "sore" in the left groin, for a week. No history of a previous trauma could be obtained. Examination showed a gangrenous patch with sinuous edges and about three by two inches in extent, surrounded by an inflammatory areola about half an inch in width. It commenced in the groin where the site of ulceration was occupied by a blackish scab and was apparently spreading upwards mainly on the abdominal wall. This more recent ulceration showed what were evidently sloughing portions of skin of a dirty white color. There was nothing to be seen approaching the appearance of a membrane and the edges gradually merged into healthy skin, but in the more central portion the loss of substance was considerable. The left labium majus was greatly swollen, but no trace of ulceration could be found upon it. No glandular enlargement was noted. A culture was made from the surface of the gangrenous patch and true diphtheria bacilli were found. The case resulted fatally on the forty-first day of the disease, after a course in which evidences of a profound poisoning of the nervous system were manifest.

Berliner klinische Wochenschrift, April 17, 1905.

The Combination of Radiotherapy with Organotherapy. Poehl and Tarchanoff describe a method by means of which it is possible to render organic preparations such as mammin, spermin, cerebrin, thyreoidin, etc. radioactive. The first step is the preparation of radioactive absorbent cotton, and this is accomplished by forcing the air in contact with a quantity of one to one thousand radium bromide solution through tubes containing the cotton. After a quarter to half an hour the cotton becomes strongly activated, and if some of this is placed in any one of the various organopreparations it gives up its radioactivity to this. Going on Poehl's theory that these substances exert a selective action on the type of organ from which they were obtained, the authors believe that by injecting such radioactive preparations it is possible to cause the radium emanations to exercise the same selective action.

Echinococcus of the Thyroid.—Ehrhardt says that this is one of the rarest of the tumors of the thyroid and that Eiselsberg was able to collect only twenty-two cases in his monograph. The author's patient was a man of twenty-one who suffered from serious dyspnea owing to a cystic thyroid growth. In the course of the operation for its removal it became necessary to evacuate it, and thus the true nature of the tumor was revealed. As it was largely restrosternal, considerable difficulty was experienced in performing the extirpation, but it was successfully accomplished, and two years later no recurrence had taken place.

Münchener medizinische Wochenschrift, April 18, 1905.

The Treatment of Inflammatory Conditions by Means of Aspirating Apparatus.—Klapp describes various forms of apparatus to be used for the application of Bier's method of stagnation hyperemia in the treatment of such acute conditions as mastitis, furuncles, paronychia, etc. For use in cases of mastitis a large bottle may be employed, the bottom of which is cut off and the cut edges rounded. The neck is closed with a perforated stopper through which passes a tube connected with an aspirating syringe. The author reports very satisfactory results in the treatment of cases which ordinarily would be subjected to free incision and drainage. The aspiration treatment is continued from three-quarters to one hour daily for the first few days, after which sessions of from twenty minutes to thirty minutes suffice. The suction should not be vigorous enough to give pain and should be frequently interrupted to permit absorption of the disease products. If pus is already present the abscess is opened by a very small incision and suction applied at once. The treatment relieves the pain almost immediately, and brings about a cure at least as promptly as the old method, while the patient is spared the suffering and discomfort attendant on a cutting operation with its subsequent dressings and scarring. The same principles are made use of in the treatment of other acute superficial infections in all parts of the body, by means of suitable smaller glass cups which are exhausted either with a syringe or by rubber bulbs and the results are said to be highly satisfactory.

A Fecal Tumor Simulating a Fibroma.—Wiener's patient presented a hard tumor the size of the fist behind the uterus and slightly movable. Defecation had been painful but it was rare for a day to pass without a movement. No fecal masses could be felt from the rectum, the ovaries were not palpable and a diagnosis was made of either pedunculated uterine fibroid or ovarian fibroma. About ten days later, just before a laparotomy was to be done, another examination was made and it was found that the tumor was much lower down, was doughy in consistency, and the ovaries could be identified. The operation was called off and in the course of the next few days large quantities of feces were expelled, causing the complete disappearance of the mass. The author says that owing to the vigorous ante-operation scrubbing and catharsis, sufficiently active peristalsis was started to move the impaction downward and so enable the diagnosis to be made, and he points out the great importance of making a bimanual examination immediately before every operation.

Death Following the Application of Boric Acid Ointment to a Burn.—Dopfer prescribed the official ten per cent. boric

acid ointment for a two-year-old child, whose arm had been scalded. Several days later he was called again and found the child in collapse and moribund. The injured surface was 12 cm. by 3 cm. and the retê Malphigii was exposed, no granulations having formed. The entire body except the head was covered with a scarlatina-like rash which, over the hands and feet, was of blue-black hue and petechial in appearance. The temperature was subnormal. According to the parents the child had not suffered greatly from the burn, but a few hours after the ointment had first been applied the rash appeared and the little patient began to give evidence of prostration. The symptoms steadily progressed until death occurred shortly after Dopfer's arrival. The author calls attention to the fact that although boric acid is usually regarded as harmless, it evidently should be applied with caution to large wound surfaces, especially in children, and particularly if no granulations are present.

Deutsche medizinische Wochenschrift, April 20, 1905.

Technique of the Alexander Adams Operation.—Robbers describes as follows his method of performing the operation, which he considers less likely to lead to injury of neighboring structures. The usual skin incision, 6 to 7 cm. in length, is made parallel to Poupart's ligament, and the external ring is carefully laid bare. The ligament is identified at its exit from the ring and is clamped. The external oblique is split up in the direction of its fibers and the cut edges are well retracted. By traction on the clamp the ligament is made tense and is then freed at a point about 3 cm. from the external ring, where it can usually be readily identified and is not easily torn off. Its light color and the ease with which it yields to traction with the forceps, distinguish it. It is then drawn forward and the peritoneal investment stripped back by blunt dissection. It is better to tear off the distal end than to cut it, as otherwise a small vessel is sure to bleed. In case it is impossible to find the round ligaments the author recommends ventrofixation by means of the suprapubic transverse incision.

A Remarkable Collection of Foreign Bodies in Appendicitis.—Rebentisch describes the case of a woman of seventy-four who came under observation with what appeared to be an inflamed hernia. The acuteness of the symptoms made it seem likely that the intestine was involved, but the absence of symptoms of obstruction rendered it probable that it was the appendix that was concerned. On operation under local anesthesia, this was found to be the case, and on separating the gangrenous appendix from its adhesions it burst open and a quantity of pus and small foreign bodies escaped. These were over a hundred in number and comprised two grape seeds, two other seeds, six fragments of enamel, three bone spicules, a bit of wood, several small pieces of gravel, numerous fragments of gallstones, and a large number of small, light brown, facetted concretions. These had a white, chalky nucleus, and were composed mainly of calcium phosphate and carbonate. The author believes that they were true enteroliths and that they were formed *in situ*. At a secondary operation the radical cure of the femoral hernia was successfully accomplished.

Annals of Surgery, April, 1905.

Studies on the Pathology and Etiology of Obstructive Hypertrophy and Atrophy of the Prostate Gland.—The following propositions summarize the views of P. M. Pilcher: (1) Pathologically there are three types of prostates causing urinary obstruction: (*a*) The large, soft type, (*b*) the hard, small, contracted type, and (*c*) the mixed type. (2) Infection does not influence the variety of the pathological change. (3) The contracted form of prostate is not a secondary stage of the large, soft type of hypertrophied prostrate, but is distinct from it. (4) In many cases of hypertrophy of the prostrate there is present a true muscular hypertrophy. (5) In some of the atrophic cases the glandular elements diminished and the muscular elements relatively increased. (6) Gonorrhea is not an important etiological factor in the production of this disease, and there is no necessity for assuming it to be. (7) The theory of obstruction to the ducts causing passive dilatation of the glandular elements, as advanced by Ciechanowski and Crandon, does not satisfactorily explain the pathological findings. (8) Hypertrophy of the prostate results from glandular overgrowth, influenced by the degenerative changes of old age, and other agents which tend to produce the formation of fibrous connective tissue in an actively functionating gland.

Has the Catheter a Place in the Treatment of Chronic Prostatic Hypertrophy?—Paul Thorndike notes that radical operations on the prostate are slowly shouldering aside the catheter and other palliative methods of treatment and giving them a gradually contracting field of usefulness, but he realizes that there are some patients unfit to endure the shock of such radical methods and some who are better off with proper palliation rather than with radical intervention. Proper catheter instruction in patients who are old and obviously bad surgical risks may enable them to pass their lives in comparative comfort and with a steadily diminishing risk of infection. If such comfortable palliation ceases to be possible, the time for intervention is at hand, notwithstanding its formidable risks. Again, in younger patients there may be an atonic condition of the bladder muscle and an operation on the prostate does not better his condition at all, because it does not remove what has come to be the main (though secondary) cause of the trouble. In such cases the employment of the catheter is commendable. Such patients should use the catheter regularly and at such intervals as to prevent daily over-distension of the bladder until such time as the bladder shall rejuvenate itself to a degree which will enable it to empty itself, at least in large measure, after its obstruction is removed.

Prostatism without Enlargement of the Prostate.—C. H. Chetwood tabulates thirty-six cases. His experience leads him to conclude that contracture of the neck of the bladder is a common cause of vesical obstruction. He finds that the condition can be safely relieved and surely by means of a galvano-prostatotomy through a perineal opening. The symptoms caused by this vesical contraction constitute what has been called prostatism without enlarged prostate. The lesion is essentially a fibroid stenosis of the vesical orifice, and its cause may be found in previous chronic inflammation in front of or behind the sphincter. Gonorrhea may be the exciting cause. The contraction may occur in the young as well as in the old. Chetwood calls attention to the fact that there is much confusion in the minds of some surgeons even at the present day between the two conditions of vesical neck contracture and prostatic hypertrophy.

Suprapubic Prostatectomy without Ether or Chloroform.—J. Wiener, Jr., declares that this operation can be safely undertaken under nitrous oxide gas even in the most desperate cases. He states that neither nephritis, diabetes, cystitis nor advanced old age are contraindications. Any man who is able to take gas for ten minutes can have the operation safely performed. Eleven personal cases are reported by the author, who counsels against instrumentation to urethra or bladder before operation. The author does not maintain that this particular operation is the most desirable one in every case. He has, however, lost no case and has never seen a severe hemorrhage, bad infection or any shock follow the operation. He denies that the operation itself has any injurious effect on the sexual capacity. No longer time is required for the wound to heal than when the perineal route is followed. Wiener has recently had one case in which the bladder wound healed in nineteen days.

The Cause of Incontinence as a Sequel of Prostatectomy.—F. W. Ruggles finds the cause of incontinence under the conditions named as due to a nerve which runs nearer the prostate than is usually assumed, being distributed to the external vesical sphincter. It seems to him that this theory of a nerve supply running close to the prostate and sometimes injured in the strenuous manipulations attending its removal, must be true, or else the injury must be looked for in the operation of the membranous urethra itself. This is accompanied, nearly always, by great stretching and tearing of the posterior urethra, sufficient to permit the exploration of the bladder with the finger, the passage of instruments and even the extraction of calculi. In these manipulations, especially at the hands of inexperienced or bungling operators, there is certainly great damage done to the external sphincter muscle, and, in addition, its nerve supply may be totally or partially cut off, especially if the incision is not made exactly in the median raphe. Also to be considered is the fact that pressure is capable of producing paralysis. For instance, the very trifling pressure on the ulnar nerve produced by sitting in a chair with padded arms will, if long continued, cause, in some persons, an obstinate ulnar paralysis. It is quite conceivable that the rather violent operative procedures in prostatectomy may produce similar effects by extreme pressure for a short time. Incontinence following simple external urethrotomy, where less cutting, dilatation, and laceration are practised, is, in my personal experience and reading, very rare. His suggestions would therefore be that, if perineal prostatectomy is performed, the incision into the urethra should be made as close to the prostate as possible, exactly in the median raphe of the compressor urethræ, and the utmost care be exercised to avoid stretching and laceration of the muscles.

French and Italian Journals.

Necrosis of the Liver in a Case of Acute Uremia.—Armand Beauvy has observed at autopsy a case of scarlatinal glomerulonephritis. The lesions of the liver in this case were very interesting. The patient was a girl six years old, who had had a light but distinct attack of scarlet fever. Just after her recovery she was exposed to a rain storm and had a chill. Five days afterwards her eyelids became swollen and albumin was found in the urine. Although she was put on a milk diet, the albuminuria increased and head-

ache developed. On her entrance to the hospital there was considerable dyspnea. The face was pale and slightly cyanosed. There was slight generalized anascarca. Râles were heard at both pulmonary bases. There was no jaundice and the temperature was normal. The child died in a day or two quite suddenly. All of the organs were congested. There was slight effusion in the pleuræ. There was no pulmonary tuberculosis. Microscopically, the kidney did not show any old sclerosis. The tubules were normal and there was some albuminous exudate. The glomeruli were greatly distended. In spite of the enlargement the blood vessels were invisible in this part. This was more noticeable because the rest of the kidney was very much congested. To sum up, there was a condition of proliferative glomerulitis. About the portal region there was a slight fatty degeneration, although the cells stained well. On the contrary, in the subhepatic region the tissues were very much congested, and there was distinct necrosis. From the fact that there had been an absence of hepatic symptoms, the writer inclines towards the theory that these lesions of the liver were due to uremic poisoning.—*Bulletins et Mémoires de la Société Anatomique de Paris,* February, 1905.

Rapid Treatment of Vaginal Gonorrhea.—C. Daniels thinks that gonorrheal is the most common type of vaginitis. The lesions are located especially in the cul-de-sacs. The writer describes the following method of treatment, which is advocated by Tuffier as being the most rapid. The vagina is first carefully cleansed with a sterilized compress or a soft brush. It is then rinsed with plain boiled water. Injections are then given of six liters of a 1 to 4,000 solution of permanganate at 35° to 50°. The vagina is then tamponed with five or six large wicks of sterilized gauze, soaked with the same solution of permanganate. After twenty-four hours the wicks are withdrawn and new ones are inserted. After from twelve to twenty-four hours this treatment is completed. The patient is carefully looked after for about two weeks, although after the second day there are no more gonococci. The cul-de-sacs are painted with tincture of iodine, which is also used to disinfect the cervicouterine cavity. Daniel approves of introducing a stick of nitrate of silver into the urethra. This is immediately withdrawn. Three or four treatments, eight days apart, will effect a complete cure of the urethral infection.—*Revue Française de Médecine et de Chirurgie,* April 10, 1905.

Nervous Symptoms in the Course of Scarlatina; Leucocytosis of the Cerebrospinal Liquid.—Several observers have shown by lumbar puncture that mumps, in spite of its benignity, may affect the meninges. Dufour and Giroux have demonstrated that this is true likewise of scarlatina. Several cases in point are reported. The first patient attacked with scarlatina suffered from nasolabial herpes. There was intense headache; the pulse was 51. On the ninth day lumbar puncture was performed, and the headache diminished in severity. The liquid showed a very abundant lymphocytosis. Pressure was normal. A second patient on the seventh day of the illness showed a narrowing of the palpebral fissure on the right side with depression of the ocular globe. There was a slight bilateral myosis without inequality of the pupils. There was also a slight degree of facial paresis. On the eleventh day lumbar puncture was practised. In the liquid there were found albumen, lymphocytes, and polynuclears. Recovery took place. In the third case numerous lymphoctyes were found. The patient recovered.—*Gazette des Hôpitaux Civiles et Militaires,* April 4, 1905.

Malady of Recklinghausen and Arrest of Development of the Bones.—Hallopeau and Jeanselme have had two patients in whom besides the ordinary lesions of the disease of Recklinghausen, there was an absence of an important bony segment. In one the fibula was lacking. The *x*-ray showed that only the epiphyses were present. The diaphyses were completely lacking. These cases show that an arrest of development is intimately connected with the disease of Recklinghausen, and they prove that this disease can affect all parts of the economy.—*Le Bulletin Médical,* April 19, 1905.

Functional Treatment of Mild Scoliosis.—A. Codivilla tells us that every case of scoliosis, no matter how slight, should be treated, because it predisposes to tuberculosis, and because it indicates a morbid condition of health. Instructors of all kinds should be on their guard to detect these slight cases, and have them placed under treatment. Research has demonstrated that scoliosis is a form of contracture, and for such conditions the rational treatment is active and passive movements. The apparatus should permit of movements in the deformed portions of the spine alone, the normal portions remaining fixed. The best results were obtained by the author with the apparatus of Schulten. The apparatus of Zander is easier of application and also gives excellent results.—*Rivista Critica di Clinica Medica,* April 1, 1905.

Action of Adrenal Extract on the Renal Parenchyma.—Luigi Vaccari made experiments on rabbits to determine the effects of injection of adrenal extract before operations on the kidneys, making a careful microscopical examination from one day to ten days after killing the animals. He injected adrenal extract into one kidney, salt solution into the other, and then performed the same operation on the two kidneys. He concludes that adrenal extract far from preventing the bad effects of operation on the renal parenchyma, rather exaggerates them, having a deleterious action on the cells themselves, and influencing their nutrition unfavorably. Therefore, the use of this substance before operations on the kidneys does not decrease the hemorrhage, and acts unfavorably as well.—*Il Policlinico,* April, 1905.

Treatment of Intestinal Obstruction.—Ferdinando Gangitano gives us his experience of the use of injections of atropine in case of intestinal obstruction. He includes 12 cases. On the use of this drug there have been the most opposite opinions given by eminent surgeons. In nine cases the author made use of hypodermic injections of atropine, the cases being all of a nature in which the symptoms were not very urgent, nor such as to call for immediate operation to preserve life. The dose varied from 1 to 6 milligrammes, and no bad effects were noted. The intervals between the injections were from one-half to one hour. In general there was a beneficial effect on the pains, and the vomiting. In two cases the obstruction was removed entirely. The author believes that the use atropine merits the attention of surgeons. In some cases the apparent improvement is followed by a worse condition, and operation becomes necessary. Hence the cases for its use should be selected with care, and it should not be kept up more than 7-8 hours if relief is not obtained. An accurate diagnosis is necessary. It is most useful in cases in which the obstruction is fecal.—*La Riforma Medico,* April 15, 1905.

Bacillus of Koch in the Blood.—Ch. Lesieur, in speaking of his technique, states that the obstacle which always has to be avoided is the formation of clot in the blood which is experimented with. In the course of his experiments, he has always observed that Koch's bacillus is rapidly taken up by the organs and destroyed by the leucocytes, and that it disappears from the general circulation in about fifteen minutes, on the average. As to the clinical results, of thirty patients, six only have shown positive results. In one of these, tuberculosis has been produced in a guinea pig by intraperitoneal inoculation with blood taken from the living patient. Tuberculosis bacillaemia and its consequences, whether in the course of experiment or in the course of chronic phthisis, are phenomena which are very transitory. The direct examination of blood is not the method of choice. It is useful for diagnostic purposes only if it is positive, which happens in a very small number of cases.—*Lyon Médical,* April 16, 1905.

Two Cases of Sclerosis of the Coronary Arteries.—Marchiafava presents two new cases of sclerosis of the coronary arteries, which constitutes a group by themselves, because in one case there was obliteration of long standing of the descending branch of the left coronary artery, and in the other old obliteration of a bifurcation of the same artery, and marked stenosis of the circumflex artery. He presents the anatomical specimens and gives the histories of the two cases, both of which died, and gives the anatomical findings, from which he deduced the conclusion that grave distrophic alterations of the walls of the left ventricles, which existed in both cases, are a sufficient cause for the cardiac insufficiency, from which neither of the patients had experienced attacks of angina pectoris.—*La Riforma Medica,* April 8, 1905.

Simulation Considered as a Biological and Sociological Phenomenon.—Edmondo Grombetta tells us that it has been shown that simulation is an inevitable episode of the struggle for existence, and a biological and sociological phenomenon of great importance. Ingegneros goes so far as to say that it is encountered everywhere in organic and superorganic life, and is a useful aid in the struggle for existence, a result of the natural adaptation to the surroundings. It is always a means to this end, to know how to live is to know how to simulate. Man succeeds in life in proportion as he knows how to simulate successfully. As we rise in the scale of life violence grows of less value and deception of more value. Our author does not go quite as far as Ingegneros, whom he criticizes for giving as the reason for simulation of disease among soldiers a high moral position, taken as a result of the conviction that war is wrong in the present age of the world, and that the country should not be preserved under its present form of government. The author says that the average peasant, laborer, or student does not all think of these things. He simulates because he does not wish to leave his fields, his work, his studies; he cannot leave his family, change his environment or his plans; he does not wish to meet danger or death.—*Giornale Medico del Regio Esercito e della Marina,* March, 1905.

Book Reviews.

THE VERMIFORM APPENDIX AND ITS DISEASES. By HOWARD A. KELLY, A.B., M.D., Professor of Gynecology in the Johns Hopkins University, Baltimore, and E. HURDON, M.D., Assistant in Gynecology in the Johns Hopkins University, Baltimore. With 399 original illustrations, some in colors, and 3 lithographic plates. Philadelphia and London: W. B. Saunders & Co. 1905.

THE appearance of this volume is as important a contribution to the history of appendicitis as the senior author's "Operative Gynecology" was to the annals of that branch of abdominal surgery when it was published a decade ago. Since that time but few changes have been made in the teachings of the latter book, and it is likely that the lore of appendicitis as here expressed will remain for the most part unaltered for at least the same period of time. The first three chapters are devoted to the history of the disease. Mr. Brödel, the well-known medical illustrator, has written the succeeding four chapters on the anatomy of the appendix, and these with his illustrations throughout the book show the value of the combination of scientific knowledge with the art of the draughtsman. Then come three chapters on the physiology of the organ and its post-mortem appearances; the following five chapters deal with bacteriology and pathology, and the remainder of the book, comprising twenty chapters, is devoted to appendicitis in all its various aspects of etiology, diagnosis, treatment, and relation to other conditions. A large portion of the text, as is natural, is devoted to operative methods. These are amply discussed, all the recognized procedures being given and the authors' preferences or innovations described. Kelly uses the McBurney incision in nonsuppurative cases and Battle's semilunar incision when pus must be evacuated and there is necessity for extensive packing with gauze. He adopts a radical stand in regard to drainage, and advises that in all doubtful cases the wound be left partly open. Washed-out iodoform gauze is considered the best drainage material, and is used in large amount; the presence in the exudate of colon bacilli on the one hand or of cocci on the other indicating whether ordinary precautions will suffice or there must be a wider drain with everything left open. Kelly's technique of dealing with the stump by means of special crushing forceps and the cautery is clearly described and figured. In harmony with the opinion of most surgeons the authors believe that the healthy appendix should not be molested in the course of an operation on some other part, while if adherent it should be removed. The standpoint adopted in regard to early operation is also that of most surgeons in this country. It seems strange in the sections on leucocytosis as an aid to diagnosis, not to find any mention of the value of differential counts. Even in so brief a review of this reference should be made to the illustrations which, by reason of their profusion, beauty, and interest, contribute to an unusual degree to the value of the book.

THE PRACTICAL MEDICINE SERIES OF YEAR BOOKS. Comprising ten volumes on the Year's Progress in Medicine and Surgery. Under the general editorial charge of GUSTAVUS P. HEAD, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate School. Volume I, General Medicine. Edited by FRANK BILLINGS, M.S., M.D. Head of Medical Department and Dean of the Faculty of Rush Medical College, Chicago; and J. H. SALISBURY, M.D., Professor of Medicine, Chicago Clinical School. Volume II, General Surgery. Edited by JOHN B. MURPHY, M.D., Professor of Surgery, Northampton University Medical School. Series, 1905. Chicago: The Year Book Publishers, 1905.

THIS new series of the well-known year-books issued by the Chicago publishers presents the same features as have characterized previous annual issues. Volume I, dealing with general medicine, contains a review of progress in this field during the year 1904. The book is written chiefly from the viewpoint of the general practitioner, and is a convenient desk manual. No attempts have been made to offer the complete literature of any subject, but well-selected articles on each theme are abstracted, many of them very fully, and annotated by the editors. Good judgment has been used in allotting the space available, so that important subjects, such as tuberculosis, pneumonia, gout, diabetes, nephritis, cardiac lesions, etc., receive detailed attention, although considerable space is devoted to such themes as splenic anemia and spondylitis deformans, which have figured much of late in literature.

Volume II comprises general surgery in all its departments. It is intended to reflect the progress of surgery during the year 1904, and the name of the editor is sufficient guarantee that the ground has been satisfactorily covered. A number of illustrations of instruments, operations, etc., are included. The treatment of the subject is that which characterized the former edition, namely, abstracts and annotations are given of selected articles by writers with the greatest experience in their individual field. In this way the best and most authentic information on each topic is presented, and the value of the work as a reference book is enhanced. All the important subjects have been well covered, and the book is of undoubted value to both physicians and surgeons.

WHARTON & STILLÉ'S MEDICAL JURISPRUDENCE. Vol II, Poisons. By ROBERT AMORY, A.M., M.D., President of the Sixth National Convention of 1880 for Revising the U. S. Pharmacopœia; formerly Professor of Physiology, Bowdoin Medical College, and Lecturer on the Physiological Action of Drugs, Harvard Medical School, etc., and ROBERT L. EMERSON, A.B., M.D., Instructor in Physiological Chemistry Medical School of Harvard University; Assistant in Clinical Pathology, Boston City Hospital, etc. Fifth Edition. Rochester, N. Y.: The Lawyers' Cooperative Publishing Co. 1905.

IN passing through the various editions since its first appearance in 1873, this treatise on toxicology has undergone many changes, so that now but little of the classical original remains. As it stands, the work is in every respect representative of modern methods for the detection and identification of poisons, and though designed primarily as an aid in medicolegal work, it should prove valuable for reference to practitioners as well. The old plan or arrangement in which the drugs are grouped according to their physiological actions has been discarded, and a scheme adopted which more nearly follows physical and chemical properties so as to facilitate investigations on the nature of poisons detected after death. The recent researches on the toxicology of wood alcohol have been incorporated, as well as a consideration of the biological tests for the identification of blood and seminal stains. Although, as is natural from its scope, but little attention is devoted to the subject of treatment, the book is such a mine of information on the physical properties of poisons, the symptoms produced in overdose, post-mortem appearances, tests of identity, means of detection, etc., that it should prove of value to practitioners as well as to those especially interested in forensic medicine.

THE PHYSICAL CULTURE LIFE. A Guide for All Who Seek the Simple Laws of Abounding Health. By H. IRVING HANCOCK, author of "Japanese Physical Training," "Physical Training for Women by Japanese Methods," "Physical Training for Children by Japanese Methods," "Jiu-Jitsu Combat Tricks," "Life at West Point," etc. Illustrated. New York and London: G. P. Putnam's Sons, 1905.

THE present volume presents, as the author says in his preface, the real aims and methods of the physical-culture movement so prominent just now in England and in the United States. The underlying idea is that the physical-culture life is not complex, but simple, natural, and sensible. The writer disclaims any allegiance to fads, so many of which are advocated nowadays in the search for health. He considers the effect of exercise on muscles and the tests of muscular weakness and strength. The importance of the right use of air, water, and food in their relations to body growth is emphasized. The simpler outdoor pleasures—walking, riding, swimming, rowing, and bicycle riding—are discussed from various points of view. One chapter is devoted to Non-Competitive Track Athletics for Health, Not for Records, while another one considers the Safe Non-Competitive Idea Applied to Field Athletics. The writer concludes this excellent common-sense manual with the consideration of the mental factors in physical culture.

ERRORS OF REFRACTION AND THEIR TREATMENT. A Clinical Pocketbook for Practitioners and Students. By CHARLES BLAIR, M.D., Fellow of the Royal College of Surgeons of England; Surgeon to the Western Ophthalmic Hospital, London; Ophthalmic Surgeon to the Royal Hospital, Richmond. Bristol: John Wright & Co. London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd. 1905.

THE author of this neat little book of one hundred pages has given us quite a complete primer on the elements of refraction. It is written in a simple and interesting style, and is clear and comprehensible alike to the general practitioner and to the beginner in his study of optics.

THE BRITISH JOURNAL OF CHILDREN'S DISEASES. Edited by GEORGE CARPENTER, M.D. Vol. I. London: Adlard & Son, 1904.

THE editor in his introduction states that the object of this journal will be to keep its readers in touch with advances in knowledge in all that relates to the study of disease in children, whether of a scientific or a practical nature. Not only disease itself, but the prevention of disease is considered. The volume is well illustrated. It will prove of value to all interested in pediatrics. Several of the articles have already appeared in abstracts in the MEDICAL RECORD.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF CALIFORNIA.

(Special Report to the MEDICAL RECORD.)

Thirty-fifth Annual Meeting, held April 18, 19, and 20, at Riverside.

THE PRESIDENT, DR. FRANK L. ADAMS IN THE CHAIR.

THE attendance was the largest in the history of the society, and the interest manifested by those present was correspondingly great. After the address of welcome, by Dr. W. W. Roblee, president of the Riverside County Medical Society, the remainder of the first morning session was devoted to

A Symposium on Typhoid Fever.—Dr. C. M. COOPER of San Francisco read on the pathology of the disease, reviewing in an interesting and thorough manner all the lesions and their relation to the infection.

Dr. F. C. E. MATTISON of Pasadena read a paper on the surgery of typhoid fever, general and immediate, in which an impartial discussion of the best methods of dealing with perforation and other accidents and complications was presented.

Dr. S. J. HUNKIN of San Francisco dealt particularly with the rare affections of the joints, and reported a case in which the hip-joint had become infected, his diagnosis having been confirmed by the serum reaction, with blood from several patients, as well as with the blood of an immunized guinea-pig.

Dr. RAY L. WILBUR of Stamford University read a paper on the routine treatment and complications. After reviewing the general clinical characteristics of the disease, the essayist addressed himself to the more important methods of treatment, including the use of serum and the other so-called specific methods. While he hoped for good results in the future from the serum treatment, he regarded it as purely experimental at the present time. Until something better shall have been found, he considered the most advisable plan the adoption of proper dietetic, hydrotherapeutic and symptomatic measures. Of the utmost importance, however, is the attendance of a suitable nurse, a well ventilated, large and properly arranged room, a bed of proper size, height, width, etc., and the presence of supplies to be used in cases of emergency, a thing too often overlooked. He recognized milk as the basis of the proper food, and in many cases the best for exclusive use. Broths, gruels, and solid foods were also considered with reference to their use in convalescence or in particular cases. Of great importance is an abundant supply of pure water, both for drink and for external use. The proper application of the full bath, the abdominal coil, the ice-cap, and sponge baths was well brought out. The general medicinal treatment, the use of intestinal antiseptics, antipyretics, stimulants, diuretics and sedatives, and methods of regulating the action of the bowels were all discussed. Of particular interest also was the consideration of complications, the statistics of which were given with commendable fulness, together with the recorded mortality. Perforation, hemorrhage, nephritis, myocarditis, and late arterio-sclerosis were referred to as important remote factors in the mortality.

Dr. GEORGE B. ROWELL of San Bernardino read a paper on the accessory treatment, in which much the same course of treatment was recommended, but more directly in reference to the management of special symptoms and complications. The serum treatment, the use of antiseptics, and the feeding of the patient were all dealt with.

Is Pulmonary Tuberculosis a Menace to the Health of Los Angeles?—Dr. GEORGE H. KRESS, of Los Angeles, in his paper, in addition to the points of purely local interest, called attention to the facts that the mortality from this disease in Los Angeles is second in the United States only to that of San Antonio. Twenty-five per cent. of the cases that die have been the subjects of charity. The general death rate of the city is exceptionally low, and it was made evident that the excessively high rate from tuberculosis is due to the influx of hopeless cases from other States. This was further established by the records of short residence in this State. Among people who have resided in the city many years, the mortality is low. The influence of the cheap lodging house, lack of sanitary measures, and poor food among the poor immigrants was also shown. As measures for relief, he advocated compulsory notification of the disease, ordinances for the regulation of lodging houses, the establishment of municipal dispensaries, sanatoria and hospitals exclusively for consumptives.

The Heart in Tuberculosis.—Dr. WOODS HUTCHINSON of Portland, Oregon, called attention to the manner in which the profession has been led astray from time to time by fallacious teaching with regard to the most important factors in the production of tuberculosis. At one time it was the dietetic and digestive ideas, at another time the one thing was infection, then the disease was regarded as purely pulmonary, and every possible contrivance was devised for its treatment. Now we resort more to methods which ignore the bacilli and ignore the lungs. He regarded the size and action of the heart as of much greater importance in the causation of tuberculosis than the condition of the lungs, and the pulse as a better guide in diagnosis than any other symptom. Referring to the size of the heart, he stated that a study of the susceptibility to the disease among lower animals confirmed the previous statement. The smaller the heart in ratio to the weight of the animal, the greater was the liability of the animal to infection. The sheep is practically immune, with a heart that is about one one-hundredth the weight of the animal. The horse also is practically immune, the weight of the heart being about one ninetieth that of the animal; goats have the same immunity, for the same reason. On the other hand, the antelope, with a heart weighing one one-hundred-and-fiftieth the weight of the body, takes the disease readily, and the cow, with a heart one two-hundred-and-twentieth of its body weight, is exceedingly prone to infection. He stated further that his own investigations and those of others have added strength to the assertion made by him several years ago that not the shallow, flat chest, but the narrow, long and deep chest, is typical of tubercular predisposition. The drooping of the shoulders, from weakness of the muscles, produces a false appearance of shallowness. The lung that is attacked by tuberculosis is the large lung, the lung that is not used. In this connection, however, it has been shown that the tuberculous patient takes into his lungs and uses a much larger quantity of oxygen than a person in health; there is not a deficiency of oxygen, but an excess of it, so that nutrition is interfered with by the excessive oxidation. With reference to treatment, he advocated the open-air method, keeping the patient absolutely at rest and forcing the feeding to such an extent that the nutrition of the body will be kept up and the size of the body made to correspond more closely to that of the lungs, at the same time reducing the excessive oxidation.

A Brief Consideration of Some of the Difficulties Attending the Artificial Feeding of Infants.—D. A. B. COWAN of Fresno, after reviewing the many perplexing things to be considered in the selection of a suitable food for the young bottle-fed infant, he concluded that cow's milk, without particular reference to its being obtained from a single animal or from the herd, is the best foundation for the food. It should, however, be as fresh as possible, and in some cases the addition of a cereal, to prevent firm coagulation of the casein, and sometimes also an alkali is advisable.

The Adams-Stokes Syndrome.—Dr. H. S. GORDON of Santa Ana then read on this subject and reported two cases. the views of Stokes, Adams, and other authorities with reference to the origin and nature of the condition were reviewed. He thought that the usual definition was too narrow, as the syndrome may occur in any one of several conditions of the heart and nervous system, and a great

variety of symptoms may be observed in it. While the disease is more common in adult life, it may occur at any time from infancy to advanced age. The frequency of the attacks also vary greatly; in one of his own cases there were sixty in a single day. Bradycardia he regarded as the essential symptom. Arteriosclerosis he did not regard as necessary in its production. In one case he had administered digitalis with apparent benefit, although it is theoretically contraindicated.

Dr. Woods Hutchinson, in discussing the paper, thought that the whole condition can be referred to disease or injury of the spinal accessory nerve. He had seen two cases. In one of them, before any attack had occurred, the man had fallen and injured his spine severely, close to the occiput. The second case had been in a serious railroad accident and received an injury of the neck in the cervical region. The attacks in this case came on immediately and became more and more numerous in their recurrence, and the spasms affected parts supplied by every branch of the spinal accessory nerve.

Uncinariasis in California.—Dr. Herbert Gunn of San Francisco read this paper, which was based on the observation of sixty cases. No case has been known to have originated in the State of California, but the disease is being imported daily, chiefly from Hawaii. Since the infested laborers spread all over the State, there is great danger of place-infection, and that the disease will soon appear sporadically or in epidemic form. The importance of early recognition and correct treatment were emphasized. Specimens of the hook-worm were exhibited, and the ova, some containing living embryos, were shown under the microscope. The essayist thought the thymol treatment the best, but had not found it entirely satisfactory. There was always a tendency to recurrence of the disease in a few weeks, and it was difficult to induce the ignorant class, who generally harbored the worms, to remain for completion of the treatment.

Dr. Philip King Brown of San Francisco urged methods for quarantining the immigrants until they could be freed from infection.

Human Glanders, with Report of a Case.—Dr. W. F. Cheney of San Francisco read this paper. After a general treatment of the subject, the speaker narrated the case of a man who became infected from a horse not known to have the disease. The lesions were not typical for a time, but the diagnosis was established by staining and culture methods. Inoculation experiments were not successful. The horse was found to be infected by the same methods. Several other cases were referred to. The discussion revealed the fact that glanders is comparatively frequent among the lower animals in the State, but hat human beings are not often infected, owing to the early destruction of the diseased animals.

A Case of Poisoning by Ceonothus Velutinus was reported by Dr. R. F. Rooney of Auburn. This plant, known also as "honey dew," or "snow brush," grows abundantly in northern California, and in a slightly different variety in Oregon. It is not considered poisonous, but in the case reported it was the only source discoverable. Repeated attacks of a rash, resembling that of rhus-poisoning, had occurred on exposed surfaces. Rhus is unknown, however, in the region.

Hyoscine Hydrobromate in the Treatment of the Morphine Habit.—Dr. R. E. Bering, of Tulare, described this method in detail. He favored the so-called elimination treatment, beginning with catharsis, a vapor bath, and strychnine hypodermically; this to be followed by withdrawal of the morphine and free administration of the hyoscine in the usual manner.

Address of the President.—Dr. Frank L. Adams of Oakland, in this address, dealt for the most part with topics of interest to the profession of California, especially the workings of the State Board of Health and the difficulties constantly encountered by it. The best methods of dealing with tuberculosis were also discussed in an interesting and instructive manner.

The Report of the Committee on Tuberculosis was then read by Dr. F. M. Pottenger of Los Angeles. This also dealt with the needed measures for the suppression of the disease, compulsory notification, instruction of the people in prophylaxis, but especially in the need by the State of a hospital for the tuberculous poor. The committee had succeeded in having a bill passed by the legislature providing for such an institution, but the Governor had refused to sign it on account of the scarcity of funds in the State treasury.

The Hopes, Disappointments and Successes of the State Board of Health, was the subject of a report by Dr. N. K. Foster, secretary of the State Board. A history was given of the board from its organization, nearly thirty years ago, to the present time.

The Report of and Suggestions on the Work of the State Board of Medical Examiners was read by Dr. Dudley Tait, president of the board. The report served only to emphasize the fact that the California Board of Examiners is one of the most efficient in the United States.

Symposium on Diseases of the Gall-Bladder and Ducts.—Dr. H. C. Moffitt of San Francisco presented the first paper on diagnosis. It was a lucid presentation, not only of the signs and symptoms of these diseases, but of the differentiation of every possible condition that may present in the investigation of a case. An adequate review of the paper is impossible. The importance of recurrent pain in the epigastrium as a symptom of gall-stones was emphasized, but the plan is often misleading. The presence of Riedel's lobe is also important, but the essayist considered the use of the *x*-ray one of the most valuable and positive means of recognizing these concretions. It is sometimes necessary, however, to make as many as four or five exposures in order to get the best plate-results. Several excellent plates were exhibited. Jaundice is not a trustworthy indication of obstruction by gallstones. Neither can leucocytosis be depended upon to confirm the diagnosis, since it is often absent during periods of latency. Slow coagulation of the blood is of value in the differentiation of pancreatic disease.

The next paper, by Dr. Ernest B. Hoag of Pasadena, was an interesting review of the pathology of the diseases under consideration. It was briefly discussed by Dr. H. A. L. Ryfkogel of San Francisco.

This was followed by a report on "Experimental Studies on Gall-Bladder Infection," by Dr. A. J. Lartigau of San Francisco, read by Dr. Tait, in the absence of the author. After a brief review of the literature of his subject and a reference to the experimental work of others, the essayist reported his own work, very little of which can be recorded in this report. Bacteria, sand, and other foreign substances, separately or together, were introduced into the gall-bladder, and allowed to remain for longer or shorter times. The introduction of bacteria generally resulted in the production of stones, but the sand and other foreign bodies failed as a rule, unless bacteria were also present. Small stones were obtained in six weeks, but nine months or longer time was required for the development of large calculi. The gall-bladder containing stones was rarely found to contain any bacteria of a different species than those originally introduced. He could not assert that a mixed infection, as with the colon and other bacilli, resulted in an earlier production of the stones than the presence of only the one kind of microorganism. The presence of foreign bodies, as grains of sand along with the bacteria, produced the stones more rapidly; but the presence of a foreign body is not at all necessary. A partial or complete obstruction of the bile duct did not induce the formation of gallstones, except when bacteria were present. Bacteria enclosed in impervious bags led to the production of calculi, especially when the bacillus pyocyaneus was thus introduced. A number of experiments were made also with

reference to the route by which bacteria reach the liver. It was found that, while it may be possible for some bacteria to reach the organ through the bile ducts, most of them pass through the portal circulation. The author had taken the precaution, in his experiments, to use varieties of bacteria not known to have an independent existence in the gall-bladder. He observed also the possibility of infection from the peritoneum, and that trauma may act by inducing infection, with the subsequent production of stones.

Dr. Dudley Tait called attention to the importance of using proper methods of culture, referring especially to the difficulty of recoginizing the anærobes, and the impropriety of deciding that gallstones had formed in the absence of bacterial infection unless all this class of organisms, so frequently present, has been excluded.

The Value of Early Operation in Gallstone Diseases.—Dr. Emmet Rixford of San Francisco took this as his subject. Rational treatment, he said, should be based not merely upon immediate relief of symptoms and the danger of mortality, but upon a proper regard for the possibility of future complications and final results. The passage of gallstones, with relief of the attack of colic, does not constitute a cure. Medical treatment is only palliative, curative treatment is necessarily surgical. Calculi are generally found in successive crops, and the passage of a small stone does not guarantee that other stones will pass. The presence of biliary sand, if prolonged, will do as much harm as a large stone. For these reasons the propriety of an operation after an attack of gallstone colic should be seriously considered. Serious consideration should be given also to the possibility that recurrent attacks of acute indigestion, persistent colic, or indefinite pain, may be due to gallstones, and the abdomen may be opened for exploration in obscure cases. An operation may sometimes be considered as prophylactic. The cases in which gallstones have been found to have caused no symptoms are becoming few. The author thought, however, that the stones should be removed whenever found, even if they have not caused symptoms, just as the appendix is removed whenever it presents anything pathological, even in cases in which there has been no recognized disturbance by it. He thought that the medical men should be more on the lookout for gallstones, not only because they are sometimes overlooked, but because, among other reasons, the late operations are vastly more serious than those performed early. The various operations were then briefly referred to. The essayist preferred the removal of the gall-bladder when this is possible, as a primary operation.

Dr. H. C. Moffitt, in the discussion, did not fully agree with the last speaker with reference to early operations. He referred to ten cases that he had sent to the surgeons for operation. Of these, only two obtained complete relief. There are cases, he thought, which ought never to be submitted to operation, cases in which the failure of an operation can be predicted from the condition and temperament of the patient. Many of these cases get along very well without either medical or surgical treatment, if they are kept quiet and permitted to take their Carlsbad salts, or similar apperient every morning, with regulation of the diet. They are not cured, but the result is better than that of operation.

Dr. Dudley Tait called attention to the reformation of the gall-bladder after removal in lower animals, providing the cystic duct has not been excised. Several of his own experiments were reported.

Affections of the Pancreas in Their Relation to Affections of the Gall-Bladder.—Dr. A. S. Lobingier of Los Angeles read this paper. He attributed the bad results in most cases of operation on the gall-bladder to cholemia. This, he thought, could be to a great extent prevented by proper preparation of the patient through correct diet, etc., previous to the time of operation.

Treatment of Compound Fractures.—Dr. George N. Drysdale of Eureka read this paper, in which he dwelt upon the necessity of converting an infected wound into an asceptic one, and that this was possible only at the beginning, immediately after the receipt of the injury.

Adolescence in Girls.—Dr. F. R. Burnham of San Diego, in this paper, referred to the important changes in the circulation at puberty, the diversion of the blood from other parts of the uterus, with marked disturbance of other functions. While puberty in boys amounts to little more than a change of voice, it means much more to girls, and the dangers attendant are beyond comparison. He called attention also to the evils of the present system of education, as well as to the home life of the period. At school the same tasks are imposed without regard to the physiological welfare of the girl, and at home she generally ceases her outdoor exercise and romping for a more sedentary mode of living, and too often for a life of drudgery in the care of the home. He thought that coeducation ought to be suspended, or better, that the girl should be taken from school until the menstrual function has been fully established. The girl should at least be permitted to absent herself from her classes during menstruation.

Dr Charlotte Baker of San Diego, in discussing the paper, objected to the statement that puberty in the boy was little more than a change of voice. She thought that the changes were just as profound and important as those in the girl. The difference was chiefly in the habits of the boy and girl, and she thought that if girls were given the same freedom of outdoor life and comfortable clothing there would be no need of interrupting their education.

When to Operate for Fibroid Tumors of the Uterus.—Dr. Rose T. Bullard read this paper, in which she advocated operation in all cases; in the young because of sterility or the danger in childbearing, near the menopause on account of probable degeneration. Preference was expressed for myomectomy when it is practicable.

Dr. W. F. B. Wakefield of San Francisco, in discussion, agreed with the essayist in the main, and referred to the classes of cases in which the various operations are indicated.

Dr. Raymond Russ of San Francisco demonstrated a new interdental splint for the treatment of fractures of the lower jaw, presenting also a review of the former methods of treating the condition.

Plea for a More Simple Technic in Herniotomy.—Dr. F. O. Witherbee of Los Angeles said that his method was demonstrated in detail and illustrated by diagrams. He regarded it as so simple that the general practitioner was warranted in performing it, rather than leave his cases to the uncertainty of trusses. The method was a modification of the Andrews operation, the author using figure of 8 sutures, non-absorbable suture material and an external plate for their support. The operation, he said, is virtually a plastic one, with prolonged tension on the sutures, hence the necessity of non-absorbable material. He has devised the operation with special reference to the placing of the sutures in a manner that would not interfere with the circulation.

Multiple Tenotomy for the Relief of Spastic Paralysis.—Dr. A. M. Henderson, referring to the causes of spastic paralysis and the complexity of the symptoms in different cases, the most important of which are paresis of the lower extremities and exaggeration of the reflexes, the essayist recommended tenotomy and subsequent mechanical treatment in all cases in which there is any deformity due to contraction of the muscles.

Dr. Elbert Wing of Los Angeles, in discussing the paper, reviewed the more minute lesions of the cord and the consequent paralyses. In regard to treatment, he favored the division of the tendons, in order to put the stronger muscles at rest, but insisted on the importance of re-educating the patient in the use of the paralyzed members.

The Radical Cure of Umbilical Hernia.—Dr. A. W. Morton of San Francisco reviewed the influences which give us the greater liability to umbilical hernia in the male child and in the woman during childbearing pearíod. He

then discussed the advisability of operation, and demonstrated on a manakin the Mayo method, using the transverse overlapping operation. Several cases were reported. Some credit, it was said, should be given to Andrews of Chicago for this operation, since he described the method of closing the abdominal openings by the flap, although he did not apply it to umbilical hernia.

Dr. LeMoyne Wills of Los Angeles, in opening the discussion, desired to go back a little further and give credit to Champonnière of Paris, since he practised the flap method in hernia cases and introduced the mattrass suture. He did not consider Mayo's operation at all suitable to children, the cases to which his experience had been largely limited. Many of these cases, he thought, can be cured with adhesive strips and regulation of the feeding.

Dr. E. Rixford stated that the only credit claimed by Mayo for originality in his method was for having turned the flap to an angle of 90°, but it is this modification which gives success to the operation.

Surgical Treatment of Bright's Disease.—Dr. Z. T. Malaby of Pasadena read this paper. In the selection of cases, he followed Edebohls. In the examination of cases, he regarded the chemical and microscopic examination of the urine as of less importance than the physical qualities. The quantity of urine voided, and its weight, are of greater importance, and should be considered in connection with the general metabolism of the body, the condition of the heart and other organs. Increase of the quantity of night urine, he regarded as one of the most important symptoms of chronic Bright's disease during the primary stage. The result depends upon the character of the cases operated upon. In mild cases, the results are excellent. Cases of chronic nephritis, in which the kidneys are tender and painful, are benefited by decapsulation. Chronic interstitial, parenchymatous, or diffuse nephritis, "either unilateral or bilateral," may be cured, he said, as shown by reported cases. Cures have been reported, also, from decapsulation in renal hematuria, due to chronic nephritis. Reference was made also to removal of the kidney in nephrorrhagia, and it was stated that the floating kidney affected with Bright's disease should be operated upon. The importance of cystoscopic examination for determining the exact degree of disease in either kidney was dwelt upon. In conclusion, the speaker admitted that decapsulation has not been accepted as a routine method by the majority of surgeons.

Dr. E. Wing, in discussing the paper, expressed a fear that we are becoming too scientific. While he favored the acquiring of as much scientific knowledge as possible, he objected to such statements as go the rounds of the journals, that the presence of albumin and casts are not a trustworthy indication of disease of the kidneys.

Section on Genitourinary and Skin Diseases.—The program of this section included the following titles: "Erythema Keratodes," by Dr. Alexander C. Garceau, of San Francisco; "The Conveyance of Syphilis by Medical Men," by Dr. D. W. Montgomery, of San Francisco. The latter included, however, midwives and dentists with his medical men, and cautioned against the possibility of infection in skin grafting, genitourinary examinations, the use of the nitrate of silver stick, and catheterization of the eustachian tube. Dr. A. B. Grosse read on the "Uses and Abuses of the *X*-Rays," and Dr. W. Lehman, also of San Francsico, on the "Indications for Roentgen Therapy." He regarded skin diseases as the main field for the rays. The work of the section was concluded with a paper on the "Practical Application of Functional Diagnosis in Unilateral Kidney Lesions," by Drs. M. Krotoszyner and W. P. Willard, of San Francisco. After a brief review of the older and less accurate methods, attention was given to cystoscopy, ureteral catheterization, cryoscopy, the phloridzin test, that for urea, and the microscopal findings.

Section on the Eye, Ear, Nose, and Throat.—The following papers were read: "Skiascopy," by Dr. F. D. Bullard, of Los Angeles; "Adenoids from the Standpoint of the Parent and the General Practitioner," by Dr. R. L. Doig, of San Diego; "A Case of Cerebral Abscess Following Acute Suppurative Otitis Media with Mastoiditis," by Dr. Hill Hastings, of Los Angeles, and "The Relation of Chronic Otitis Media to Other Diseases of the Ear, and the Operative Treatment," by Dr. F. C. Welty, of San Francisco.

Officers.—The society adjourned, to meet next at San Francisco. The following officers were elected: *President*, Dr. R. F. Rooney of Auburn; *Vice-President*, Dr. W. W. Roblee of Riverside; *Secretary*, Dr. Philip Mills Jones of San Francisco.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 20, 1905.

The President, Dr. Charles L. Dana, in the Chair.

The Treatment of Epidemic Cerebrospinal Meningitis with Injections (Chiefly Intraspinous) of Diphtheria Antitoxin.—Dr. George L. Peabody read this paper. (See page 735.)

Dr. W. K. Draper said that thirty cases of cerebrospinal meningitis had been treated during the present epidemic in the First Medical Division of Bellevue Hospital. Of these, seventeen had died, two were discharged, and eleven were still in the hospital. Of the thirty cases, ten had been treated with diphtheria antitoxin, which in every instance was given subcutaneously. Of these ten, seven died, and only two of them lived more than six or seven days. Three of the patients were still in the wards, one in good condition; two in fair condition. One would probably recover. Two of the thirty cases were treated with plain horse serum; one of these was now dying; the other was in fairly good condition. Of the eighteen treated on general principles, ten died, two were discharged unimproved, and the other six were still in the wards, four of them in a serious condition, while the other two were likely to recover. Dr. Draper said their experience with diphtheria antitoxin in the treatment of cerebrospinal meningitis at Bellevue Hospital had led them to the same conclusion as that expressed by Dr. Peabody, namely, that it had no influence on the disease whatever.

Dr. Francis P. Kinnicut said the experience with the antitoxin treatment in the Presbyterian Hospital had been very similar to that reported by Dr. Peabody. The total number of cases of cerebrospinal meningitis received into the wards since January 1st, 1905, was forty-three; the number of deaths, thirty-two. Two cases were cured; nine were still in the hospital. There had been ten cases treated with antitoxin; of these, six had died and four were still in the hospital with a very grave prognosis. The intraspinous method was used in two cases. In the remaining eight the antitoxin was given by the usual subcutaneous method. Of the two patients who had recovered, one was improving at the time of his admission to the hospital, and was given but a single injection of the antitoxin. The other did not receive it.

Dr. William M. Leszynsky said that thirty-five cases of cerebrospinal meningitis had been treated during the present epidemic in the Lebanon Hospital, with a mortality of 45 per cent. In only one case was diphtheria antitoxin used, and the only result was the production of a giant urticaria. In that instance, the remedy was given subcutaneously. The patient died.

Dr. H. P. Loomis said that forty-two cases had been treated in the New York Hospital, with a mortality of 70 per cent. Diphtheria antitoxin was used early in eight cases, commencing with a dose of about 10,000 units in adults, and about 6,000 in children. After experimenting with the remedy for a few weeks, it was decided to discontinue it. In not a single instance could any improvement be traced to the antitoxin, as far as the general condition of the patient was concerned, although after the first injection the number of leucocytes was doubled and there were slight temperature changes. Horse serum, which was used in three cases, produced no effect on the

leucocytes, nor any other effect. Tetanus antitoxin was used in three cases, with apparently no effect. Six cases, treated symptomatically, were discharged cured. The speaker said he had practically gone back to the old treatment of keeping the patient quiet under morphine or opium, and applying ice to the head.

Dr. Richard Van Santvoord said that at the Harlem Hospital, in the service of Dr. Richard G. Wener, where forty cases of cerebrospinal meningitis had been treated, the conclusion had been reached that diphtheria antitoxin was of no use whatever in the treatment of the disease.

The President, Dr. Dana, said that three cases of cerebrospinal meningitis had been under his observation at Bellevue Hospital. All three were admitted about the same time, and received the antitoxin treatment. In two of them the temperature fell after the first injection, then rose, and fell again after a second injection. Both these patients were now convalescing. In the third case, the injection of the antitoxin produced no appreciable effect on the temperature of the disease, but the patient was also recovering. On the face, this would show 100 per cent. of cures under the antitoxin treatment, and was a good illustration of the fallacy of the statistics. Dr. Dana said he agreed with the previous speakers regarding the uselessness of diphtheria antitoxin in cerebrospinal meningitis.

Epilepsy.—Dr. A. Jacobi reported a case of Jacksonian epilepsy in a child three and a half years old. The family history was negative. There were two older children, both in good health. The child had been nursed during the first year of life. Dentition had not been attended by any special difficulty; there was no history of rheumatism or other infectious disease, and until the onset of the present illness the personal history was unimportant, with the exception of the fact that the child suffered from congenital constipation, and an examination of the heart showed an aortic systolic murmur. About the middle of February, 1905, the child sustained a fall. It was apparently not very severe, as there was no loss of consciousness, and the child played immediately afterwards. About a week later, slight twitching of the right side of the body, together with the upper and lower extremity, was first noticed. The child was irritable and easily frightened. There was occasional palpitation, and at times the face muscles on the right side seemed to be affected. A few days later a convulsion occurred, limited to the right side. The attacks were frequently repeated, especially at night. Sleepiness was a pronounced factor in the occurrence of the paroxysms. The treatment consisted of nitroglycerin and sodium iodide, together with elevation of the foot of the bed, in order to overcome the cerebral anemia. The most probable cause of the epilepsy in this case, Dr. Jacobi said, was the valvular heart lesion with resulting cerebral embolism.

The Formal Treatment of Epilepsy.—Dr. Charles L. Dana said that while it was conceded that the colony treatment of epilepsy approached most nearly the ideal in effectiveness, it could not be applied to all classes. Many epileptics had to be treated at their homes, and for that class of persons he had gradually evolved a conventional, or, as he had termed it, a "formal" method of treatment, which seemed to produce the most satisfactory results in those cases in which a reasonable opportunity for therapeutic effort existed. That was to say, cases which were not of very long standing, and which had not already undergone serious mental deterioration, and those in which the mental and physical degeneration, at the beginning, was not of a very high grade. The features upon which emphasis must be laid in the treatment of epilepsy were: (1) The fact that the course of treatment was to last for at least two years, and that all measures prescribed were to be carried out with the greatest fidelity and exactness during that time, no matter how well the patient might seem, or how unnecessary regimen and drugs might appear to be. (2) The use of pure bromide of sodium, in combination with the glycerophosphate of sodium, so that a patient took on an average sixty grains of the bromide of sodium and twenty to thirty grains of the phosphate of sodium in twenty-four hours. To this combination the glycerophosphate of iron and a little arsenic might be added. (3) The intermittence of the medication for either one or two days in each seven. During those days the above drugs were stopped, and in their place was given, three times a day, before meals, a tumblerful of hot water, and with it an alkaline laxative. The ordinary tablet of rhubarb and soda, with nux vomica, usually answered this purpose. (4) The securing of violent physical exercise for about twenty or thirty minutes, at least three times a week. This could be obtained by some active sport in the gymnasium, by punching the bag, or by chopping or sawing wood, and should always be continued until free perspiration took place. After this exercise, the patient was given a cold bath. With delicate persons, a hot-box sweat, followed by a cool bath, three times a week, could be substituted for physical exercise. (5) The diet should be regulated. No special regimen was ordered, other than a moderate mixed diet, with the small amount of meat that was usually recommended.

Paraepilepsy.—Under this name, Dr. Dana discussed certain nervous phenomena occurring in persons of unstable system, or in those who had, perhaps, arterial changes too actively or too early begun. They consisted of vasomotor or sensory discharges, which came on with a suddenness that entitled them to be called seizures or shocks. They were practically nervous discharges, such as were seen in migraine or epilepsy. The occurrence of these sensory shocks and seizures indicated that the patient had unstable nervous centers, but not to that degree nor of that specific character shown in the severer neuroses. They might be indications only of arterial sclerosis, or disturbances in the thyroid gland, or in the gastrointestinal tract, or they might be simply a hereditary effect of the instability of the nervous cells. When they were persistent and dominant in the symptoms of the patient, they furnished an indication for treatment, for they could be controlled by bromides and by hyoscine, by nitroglycerin, by tonics, and by attention to the general health of the patient.

Dr. M. Allen Starr said that in the case reported by Dr. Jacobi the possibility of a developing neoplasm should be considered, inasmuch as neoplasms of the brain were common in early life, and often gave rise to Jacksonian epilepsy, the attacks later becoming general. Dr. Starr said that epileptics could readily be separated into different categories. There were, first, the mild cases, with long intervals between the attacks, which were slight in character. These patients showed no evidence of an organic brain lesion or other disease. In the second type, the attacks were more severe and more frequent, and interfered with the proper mental and physical development of the patient. In the third type the individual presented definite evidences of degeneracy, by which he meant certain physical and mental characteristics that would enable one to say that the individual was not up to the normal. In the first type, the comparatively healthy epileptic, it was difficult to say that there was any organic disease. In the second type, the existence of organic disease was probable, but not certain, while in the third type there was absolutely no doubt about it. The pathological examination of the brain, Dr. Starr said, was extremely difficult, and small diseased foci involving the cortex, and giving rise to Jacksonian epilepsy, might readily escape microscopical examination and only be discovered by a very careful microscopical search. The speaker said he was quite familiar with cases of epilepsy developing after the age of 60. They could almost invariably be traced to arterial changes or a thrombus, with small areas of softening which were sufficient to cause epilepsy, but would not give rise to marked mental defects. Dr. Starr said the only criticism he had to suggest to Dr. Dana's paper was in regard to the term paraepilepsy, because if a patient was told that he was suffering from anything epileptic in character the word usually gave him a decided shock. For that reason, he would rather class this group of vasomotor disturbances under some other name.

Dr. L. Pierce Clark said he thought the case reported by Dr. Jacobi was undoubtedly one of organic disease, and was not epilepsy proper. He based his opinion not so much upon the focal convulsions as upon the subsequent paresis. True idiopathic epilepsy might at times begin focally and result in paresis of the parts previously convulsed, but in an idiopathic case the paresis was but temporary, which was not so in organic epilepsy. In discussing Dr. Dana's paper, Dr. Clark said he was not in favor of intermitting the bromides in the treatment of epilepsy. The absence of attacks in the discontinuance period could not be cited as good proof of the harmlessness of the procedure, as it always took some time for the bromides to be eliminated. He had seen many cases of fatal status epilepticus precipitated by intermitting the bromides. One should skill himself to know when bromism was about to occur, and not continue such large amounts of the bromides as to necessitate a discontinuance of treatment, even for the short period of a few days. An important factor in the dietetic treatment of epilepsy was to carefully regulate the amount of starchy food ingested, as epileptic seizures were apt to follow the occurrence of starchy indigestion. As regards cathartics, the speaker said he preferred calomel to the salines, in order to increase the flow of bile in the intestinal tract, and thus reduce intestinal fermentation. He saw no reason why the term "minor epilepsy" should not be retained to designate all those bizarre manifestations which Dr. Dana had cited under the name of paraepilepsy.

Dr. B. Sachs said that so far as he knew, Jacksonian epilepsy was invariably of organic origin, with but a single exception, and that was when it occurred in the course of uremia. The fact was first brought to his attention some years ago, and he was able to confirm it only a few days ago in a case of unquestioned uremia, with complete suppression of urine in a woman who had been entirely well until the onset of an attack of acute nephritis. She had repeated convulsions, which were always limited to the face on one side, and never involved the opposite side of the body. In that case there was noting to indicate the presence of a localized neoplasm. The speaker said he had no explanation to offer for the character of the convulsive seizures in these cases. He did not agree with Dr. Clark in regard to the harmful effect of intermitting the bromides for a day or two each week, when large doses were given to control epileptic attacks. On the contrary, he thought it was a good plan, and he was in favor of going back to the old principle advised by the late Dr. Seguin, to ascertain the minimum dose of bromide that was necessary to stave off the attacks in each particular case.

Dr. J. F. Terriberry emphasized the importance of a carefully restricted diet in the treatment of epilepsy.

The Educational Treatment of Tics.—Dr. B. Sachs read a paper on this subject. He stated that everyone who had been called upon to classify functional disordered movements had found great difficulty in distinguishing between tics, habitchorea, general choreiform movements, myoclonia, paramyoclonus, and the like. The subject was complicated by the suspicion of hysteria which often arose. Furthermore, reflex neuroses had been made to include tics and many choreiform movements, although none of these were ever truly reflex in origin. If the entire series of reflex neuroses were eliminated from neurological text-books, Dr. Sachs thought that neurological science would be none the worse for it. According to our present-day conception, a tic was an involuntary movement which could for a time be controlled, or even inhibited, at will. Tic was a coordinated or systematized movement, with a definite object in view, repeated frequently and in exaggerated fashion. The frequent repetition of such movements created the habit, and the habit once established, the movements became automatic. When a tic became firmly established, the movements were not intentional. It was certain that they could be suppressed if the will to do so were strong enough and was exercised to that end. If tics were merely oddities of muscular contraction, they could be dismissed with a few words, but they had a far deeper significance. They were often associated with mental disease, and with evident psychic and motor disturbances. At times they were the first expression of mental degeneracy. They might be developed early in life, even in very young children, and if not seriously dealt with would lead to disastrous results. The simple tic might affect any group of muscles, those of the face and neck, including the platysma, being commonest. They were not merely muscular contractions, but they were the more complicated movements of winking, sniffing, whistling, shrugging of the shoulders, twisting of the neck, and so on; in children we also observed tics consisting of screaming, snapping, scratching or biting. Speech habits or speech tics were particularly distressing. In addition to these simple tics, there were what Osler had styled "superadded psychic phenomena." These were characterized by explosive, and often foul, utterances, by the repetition of words and actions, and by imperative concepts. In former days, the treatment of this condition presented great difficulty. The ordinary sedatives and the various surgical procedures which were resorted to for the cure of some of these tics were wholly unsatisfactory. The pedagogic, or educational, treatment was based entirely upon the idea that the disordered psychic and motor functions must be disciplined in various ways. It might be called the common sense treatment, and had been practiced for years. The essence of it was to make the patient stop the movement if he could, and that he should perform systematic movements entirely opposed to those involved in the tic. The French and Germans had given dignified names to these therapeutic procedures, and had apparently enhanced their value thereby. After carefully regulated and gradually increasing periods of immobility, the patient should be subjected to well disciplined movements, particularly of the muscles in the region in which the tic occurred. Dr. Sachs believed that if this educational plan of treatment was to be a success, it could be carried out only at a private hospital or in the home of the patient, if the patient could be isolated and placed under the care of a competent nurse or younger physician. The exact exercises would vary according to the special character of the tic.

Dr. Henderson B. Deady said that in the treatment of the class of cases described in Dr. Sachs' paper, he was inclined to lay most stress upon improving their general health, and their capacity for voluntary attention, thus giving the tic a secondary place as a symptom only of a general mental condition. In all these patients, excepting the true hysterical subject of a tic, the tic was associated with a conscious psychic or ideational element, sometimes amounting to an obsession, though in many cases the patient was but vaguely conscious of the idea. In other words, the tic was always, as Dr. Sachs had maintained, a psychomotor phenomena and not a reflex. That while there were well recognized stammering tics, the usual form of stammering was not a tic, nor associated with any psychic element of the obsessional type, but was simply a failure on the part of the stammerer to maintain his attention completely on the idea which he wished to express. He maintained that the most important condition in the treatment of the subpects of tic was the recognition of their peculiar mental inability, of which the essential, practical feature was a very unstable power for voluntary attention under relatively complex conditions. Aside from the degenerate and feeble-minded class, which required institutional conditions, these patients should be treated individually. Good hygienic and easy social conditions, such as the freedom of country life offered, would often be sufficient, particularly for young children. For older children and adults we should add physical and mental exercises designed to improve their general mental condition, particularly to strengthen their powers for voluntary attention. These would consist in physical work requiring skill, such as juggling, and others involving resistance and continued effort. Also mental tasks, such as mental arithmetic,

memorizing, and geometry, all conducted under increasingly diverting conditions. After such a course of training we could direct the patient's attention specifically to the tic, in the way described by Drs. Sachs and Dana. But in addition to all this, the patient should acquire, through carefully directed introspection, a correct understanding of his mental traits, and the *modus operandi* of his tic. This would give him the incentive to spontaneous personal effort, and tend to overcome his natural "necessity for direction"; the dependence on routine and personal influence of their teacher or physician.

Dr. Leszynsky said that while the educational method of treating these cases was very satisfactory if it could be properly carried out, it could hardly be adapted to older patients. After the habit had been established many years, particularly after the age of puberty, very little could be accomplished. In any case where the spasm affected the facial muscles, the condition of the eyes and nose should be carefully looked into before advising the educational method of treatment.

Dr. L. Pierce Clark said he was in favor of the medico-pedagogical training of the tics, but he wished to speak against the use of reversal movements in their educational treatment. With every physical act, as that of flexion of the forearm, there was an accompanying increased tension of the extensor muscles which opposed the act, and which might be defined as the anthithesis tendency of the flexion movement. In the psychomotor sphere there were also latent reversal tendencies. These contrary impulses were in a great measure responsible for the hesitating and spasmodic character of the tics. This fact was admirably shown in the manner stammerers often expressed the exact contrary to the idea intended. In any case, the anthithesis tendency must not be yielded to or encouraged, as thereby the speech or facial tic would be aggravated. Hence the importance of avoiding the reversal system of training in tics. The patient should practice slow, volitional, and forcible mimic movements of the tic itself. In this way the automatic muscle movement of the tic might be brought under the control of the will, and inhibited. In other words, the patient should go with the tic and not against it in the educational training, in order to rid himself of the disorder.

Dr. A. Jacobi said that while he agreed with Dr. Sachs that many of these tics were not of a reflex character after they had once become established, he thought that in a large proportion of them the habit would have never become fixed if they had been properly treated at the start. The speaker said he could recall many cases of constant winking, shaking the shoulders, twitching one angle of the mouth, and so on, which were due to nasal catarrh or hypertrophy of the nasal mucous membrane, with or without adenoids. Dr. Jacobi said he had emphasized this point in a paper written over twenty years ago, but at that time, instead of calling them cases of tic, he had wrongly classified them as partial chorea, because some of the more aggravated ones eventually developed into chorea. Attention to the nose should never be overlooked in dealing with these cases.

Dr. Dana reported the case of a man, 51 years old, a glass-cutter by occupation. His mother was healthy. His father had been a hard drinker. The patient had always been well, but not robust, and of a nervous temperament. He had syphilis twenty years ago, but gave no history of secondary or tertiary symptoms. He had never used alcohol or tobacco to excess, and was the father of healthy children. His present trouble began at the age of 46 with a twitching of the left eye. This increased in severity, and involved all the muscles supplied by the left facial nerve in its upper and to some extent middle branch. The spasm was at times tonic, closing the eye. There was no pain. The attacks recurred every hour or two; they lasted five or ten minutes, and were increased by laughing, talking, eating, or excitement. There was no paralysis of the face. The eyes were examined and pronounced normal. When the patient was asleep, there was a rhythmical motion of the left arm. The bodily functions, aside from the above, were normal. The man was treated by a number of neurologists, who did not help him materially. He was lost sight of for ten years, and upon his return he was entirely well, and stated that he had been so for a number of years. His cure, he said, was brought about by the following procedure: Every morning he spent an hour in general calesthenic exercises, followed by a bath. With these exercises, he went through a series of movements of the eye. Standing at one side of the room, he moved his eyes slowly in a horizontal line from one angle of the room to the other, then along a vertical plane from the top of the wall to the bottom, then from the upper left to the lower right corner and back again, then from the upper right to the lower left corner and back again. These movements he went through fifty times each day.

Dr. Sachs said he differed with Dr. Deady that in the treatment of these cases the attention of the patient should not be specifically directed to the tic. This, Dr. Sachs thought, was the essential feature of the educational method of treating these cases, and was even more important than the treatment of the patient's general condition. The speaker said he agreed with Dr. Jacobi to the extent that in many of these cases the tic was of reflex origin, but once having been established, it became automatic, and the habit was formed. He did not deny that they were reflex acts, but he did deny that they were reflex motor neuroses.

Philadelphia County Medical Society.

At a stated meeting held April 12, Dr. G. G. Davis exhibited a girl 18 years old who, at the age of six had fallen into a quarry, suffering a fracture of the bones of the left upper extremity, in consequence of which there were shortening and deformity with pain from inclusion of nerve-tissue in the cicatrix. An operation recently performed to free the nerve did not relieve the pain, but as a result of a subsequent resection and the employment of an ingenious device to secure movement at the elbow-joint the usefulness of the member was greatly increased. Dr. H. E. Wetherill exhibited a stethoscope of wood with a hollow stem provided with lateral openings over which thumb and fingers can be placed for the purpose of measuring the intensity of murmurs due to valvular lesions of the heart; the instrument had projecting extension of the ear piece to fit into the auditory canal. Dr. Edmund W. Holmes exhibited "An Encysted Calculus Removed by Suprapubic Cystotomy, with Skiagraph." The patient presented symptoms of vesical calculus which could not, however, be discovered with the aid of exploring instruments. *X*-ray examination on the other hand disclosed the presence of a stone, as well as its size, and it was subsequently removed through a suprapubic opening. Dr. Holmel exhibited also an enlarged prostate gland enucleated through a perineal opening. Dr. Wm. H. Morrison read a paper entitled "Posterior Gastro-jejunostomy for Benign Stenosis of the Pylorus," and he exhibited the patient. The latter was a man who had been struck in the epigastrium by the handle of an iron implement. Later on the symptoms of gastric ulcer developed and eventually those of pyloric obstruction. Other measures failing to afford relief, the abdomen was opened and a communication established between the stomach on its posterior aspect and the adjacent jejunum by means of a Murphy button, which had not been found in the discharges at the time of report. Marked improvement followed upon the operation, with great gain in weight. Dr. F. J. Kalteyer read for Dr. J. C. Wilson a paper entitled "Cerebrospinal Fever," in which were discussed the history, epidemiology, etiology, pathology, symptomatology, diagnosis, and treatment of the disease. The discussion was participated in by Drs. Jas. Tyson A. C. Abbott, W. T. Longcope, N. B. Gwyn, Frank Woodbury, A. E. Roussel, B. F. Royer, W. S. Wadsworth.

Chicago Laryngological and Otological Society.

At the February meeting of this society, Dr. A. H. Andrews showed a young man, 19 years of age, who had had rhinolallia almost from infancy. Dr. P. J. H. Farrell read a paper on "Mastoiditis in Typhoid Patients." The history sheets and charts showed that all of them ran the typical fever curve, with rose spots on the abdomen, and Widal, diazo, and blood cultures showing typhoid bacilli, so that there was no question about the accuracy of the diagnosis. To begin with, they were not his typhoid cases, but his mastoid cases, and came to him as such for operation. Their histories were carefully taken, and there could be no question as to the accuracy of the diagnosis of typhoid. The cases showed a more severe and destructive course than was generally observed in acute cases. In all of them the necrosis was very extensive. Rapid convalescence from typhoid was most marked in all cases operated upon. Dr. Otto T. Freer read a paper on "The Maxillary Antrum; the Removal of the Greater Part of Its Nasal Wall for Empyema." The author presented a patient upon whom he had operated, and referred to the work done by Curtis in this direction, as well as to 12 cases reported by Claoué, and 7 reported by Escat. The operations in 9 of Claoué's cases, and in all of Escat's, resulted in perfect recoveries. The imperfect relief and annoyance to patient and surgeon given by alveolar drainage was considered and the reluctance of patients to consent to the radical Caldwell-Luc procedure, as this required general anesthesia and ablation of most of the facial wall. Compared to this severer method, Dr. Freer gave as the advantages of the operation he described: Operation under cocaine anesthesia instead of narcosis; the avoidance of resection of the facial wall of the antrum; the free access in spite of this given to the interior of the antrum for inspection and curettage, and the perect drainage and ventilation of the antrum obtained. While admitting that the radical operation would still be required for the severest cases, the author contended that in a great majority the nearly complete removal of the nasal wall would suffice, as it offered the advantages of the radical operation without its usually needless removal of the facial wall. Dr. Freer's patient had had empyema of the right antrum of Highmore, with intensely fetid purulent discharge for a year. Diagnosis made by transillumination and washing through a Myles trocar, which had been made to pierce the antrum in the inferior meatus. The operation was performed as follows: Local anesthesia was produced by the application (with a minute swab) of powdered cocaine. The anterior two-thirds of the right inferior turbinal were resected with Grünwald scissors and an angular knife. A long, straight trephine was then applied to the outer wall of the nose in the inferior meatus, its shank pressing the cutaneous septum, and with it the nasal tip, strongly over to the left, so that the trephine crossed the inferior meatus at an angle of about forty-five degrees. After perforating the nasal wall of the antrum with the trephine in the place indicated, a long, barrel-shaped bur was placed in the hole made and the greater part of the nasal wall of the antrum cut away. The opening was still further enlarged with Rhodes' large punch forceps. The window so made in the nasal wall of the antrum extended from above the lower border of the middle turminated body in the middle meatus downwards to the nasal floor, the base of the nasal wall of the antrum being trimmed off to the very bottom with the bur. Behind, the opening extended to the perpendicular plate of the palatal bone in front to within five-eighths of an inch of the apertura pyriformis. Large amounts of foul, coagulated pus escaped, and all of the interior of the antrum could be inspected excepting the inner surface of its facial wall. Curettage was not needed, but could have been thoroughly performed. The hemorrhage was insignificant. The interior of the antrum was palpated with the little finger. The cavity was firmly packed with a long strip of lint saturated with subnitrate of bismuth. Complete recovery ensued in about three weeks. Dr. Freer warned of the danger from arterial hemorrhage, if the posterior wall of the antrum lying in front of the spheno-maxillary fossa was pierced, or if the palate bones were included in the resection. The success of the operation depended on the making of a large opening, and especially upon the complete cutting away with the bur of the ridge between the floor of the nose and that of the antrum, as only a large opening would remain permanently.

Chicago Medical Society.

At a meeting held April 5, 1905, Dr. James B. Herrick reported a case of "Intermittent Claudication," which showed the typical symptom-complex of that affection, namely, intermittent limp or lameness, which occurs when the patient walks a greater or less distance. The patient was a Hebrew, 45 years of age, who, a little less than two years ago, noticed that in walking he had stiffness and pain in the calf of the right leg, and also some pain in the right foot. He was obliged to cease walking and to rest for a short time, after which he could continue walking again. A little later he noticed a change in the color of the feet on walking. After walking a short distance the right foot would become pale or, "as white as a sheet of paper," as the patient expressed it. Four months later he had similar symptoms in the left foot. Pain annoyed him not only in walking, but in changing the position of the foot, particularly if it were elevated, so that the blood did not circulate as freely in the foot as it should. The patient became worse, and finally, when he came under Dr. Herrick's care, two months ago, he was suffering more or less pain paroxysmally, even when he did not walk, or when he was quiet in bed, at times. About three months ago a small ulcer appeared just at the inner side of the nail on the great toe, which gradually increased in size and was the seat of more or less burning and pain, which later the patient described as almost unbearable. A small ulcer appeared under the nail of the little toe of the right foot. The ulcer on the great toe increased in size until the pain became so unbearable that an amputation of the little toe was made. This relieved the pain somewhat, but the patient has suffered a great deal since. The edges of the wound were sloughing. The symptom-complex of intermittent claudication was first described by Charcot in 1859. The patient on walking experienced pain in the calf of the right leg, with stiffness in the calf of that leg and pain in the foot, so that he walked with a limp. The other symptom was extreme pallor of the foot on walking. It was rare to find a pulsating artery in the foot. No sclerotic change could be made out in this case, either in the foot, the leg, or of the arteries of the wrist. The heart was not enlarged, and there were no physical signs of sclerotic changes in the aorta or in the coronaries. Patient had had one slight attack that might possibly be construed as an angina pectoris. The majority of cases of angina pectoris depended on sclerosis of the coronary arteries. In this patient the arteries were not sclerotic. At the time of amputation of the toe no hemostat was necessary, there being only a trifling oozing. As to the treatment, blood pressure was low; in one radial the pulse was less than 100; in the other it was 110. Strophanthus was used in large doses. Digitalis was used in combination with nitroglycerine, adrenalin and the nitrites. Warm foot-baths were used, but absolutely nothing had relieved the patient's pain except morphine, which had been absolutely necessary. Nothing in the way of treatment had seemed to give him any relief. Dr. Hugh T. Patrick also reported a case of intermittent claudication, and showed the patient, a man, 36 years of age, who gave no specific history, although he had received large doses of iodide of potassium. Dr. Robert B. Preble showed two patients with "Multiple Neurofibromata." These tumors were present in large numbers all over the body. One was a man 60 years old, the other 58 years old. In the case of 64, the tumors began to develop upon the body in places at the age of 20. There were now hundreds of them scattered over the body, many of them sessile, others pedunculated, and of varying size.

Totals	1,943	376	1,971	368

On Partial and Complete Excision of the Tongue.—Jordan Lloyd states that partial removal of the tongue may be called for in early epithelioma leucoplakia, fibroma, nevoid, papillomatous and other tumors; macroglossia, tuberculous and other ulcerations. The plan of removal may be by "wedge," "ellipse" or "lateral half," according to the physical nature of the lesion. All incisions from within the mouth are best made with scissors, and, as a rule, the long-handled, blunt-ended, straight-bladed pattern is the most convenient. It cuts to the end of its blades, and can be handled with more accuracy than either a curved or angular instrument. The mouth must be widely gagged, as a rule on the affected side, and one or more stout loops of silk ligature passed deeply through the tip of the tongue. If necessary, the cheek may be split from the labial angle backward. Before making any incision in the tongue, the surgeon should definitely decide just where and how much he is going to cut. There should be no hurry about the operation. The writer keeps the tongue extruded by means of knitting needles. When the mouth is gagged open, and ligatures passed through the tongue in the usual manner, the organ is pulled out between the teeth as far as possible, the frenum and anterior faucial pillars being divided if necessary. A stout knitting needle with blunt and smoothly rounded ends is entered close to the angle of the mouth; its point is dipped deeply downward and backward toward the root of the tongue, into which it is thrust midway between its upper and lower borders, and pushed transversely on through to the other side, where the emerging needle lies deeply in the mouth, and must be brought forward to engage on the opposite labial angle by lifting its point forward and drawing the angle of the mouth backward. The needle is then pushed on until the tongue occupies its central part. By this arrangement the tongue is kept fully extruded and exposed from tip to base. The angles of the mouth are forcibly retracted at the same time. Of the methods of complete excision, the writer speaks of Whitehead's, Syme's and Kocher's. The after-treatment of major tongue operations is as important as the operation itself. Septic broncho-pneumonia and its consequences should be guarded against. The wound should be kept as aseptic as possible by means of antiseptic applications. The patient must be sat upright in bed as soon as he recovers from the shock and the anesthetic, and must be taken regularly out of bed into an easy chair from the second or third day after operation.—*The Birmingham Medical Review.*

Pathogenesis of Lead Intoxication, Apropos of Pathological Findings in a Case.—A. Gordon discusses the pathogenesis of the affection based on the pathology of his case. Spiral cord and nerves of the upper and lower extremities were examined by him very carefully and in detail. All the phenomena observed during life of the patient can be easily explained by the pathologic findings. Gordon discusses the various theories which are now in vogue, namely: the vascular, central and peripheral. He concludes his case, shows the inadequacy of the views of those who adhere persistently to one certain theory and that lead carries its deleterious effect not to one special element of the nervous tissue, but to all its constituents simultaneously; the difference may lie in the degree, but not in the localization.—*American Medicine.*

Bossi's Method.—H. v. Bardeleben, whose dictum is to dilate the cervix if it is dilatable, and to incise it if it is resistant, expresses the view that the underlying principle of Bossi's method is untenable. Bossi in describing his instrument asserted that by its means it is possible to dilate the cervix under any condition of consistency, even in primiparæ, carrying out the procedure at such a rate of speed as the exigency of the case indicates. While v. Bardeleben admits that in selected cases it may be possible to accomplish satisfactory and safe dilatation with the instrument, he maintains that in many instances it is impossible to resort to mechanical dilatation without producing serious lacerations. In breech cases he prefers to do a combined version and to dilate by means of the breech, and in head presentations to apply axis traction forceps and dilate with the head. He cites three cases in which there is a possibility that the use of the instrument induced the fatal outcome.—*Zentralblatt für Gynäkologie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended May 6, 1905:

CYSTOSCOPY AND RENAL LAVAGE.

By FRANK M. JOHNSON, M.D.,

BOSTON, MASS.

The object of this paper is to set forth: (1) The indications demanding cystoscopy and renal lavage. (2) Rules it is wise to observe in preparing for cystoscopy. (3) Description of the modus operandi. (4) Difficulties likely to be encountered in the procedure. (5) Descriptive cases illustrating the beneficial effects of this method of treatment.

Fig. 1.—Filling the bladder.

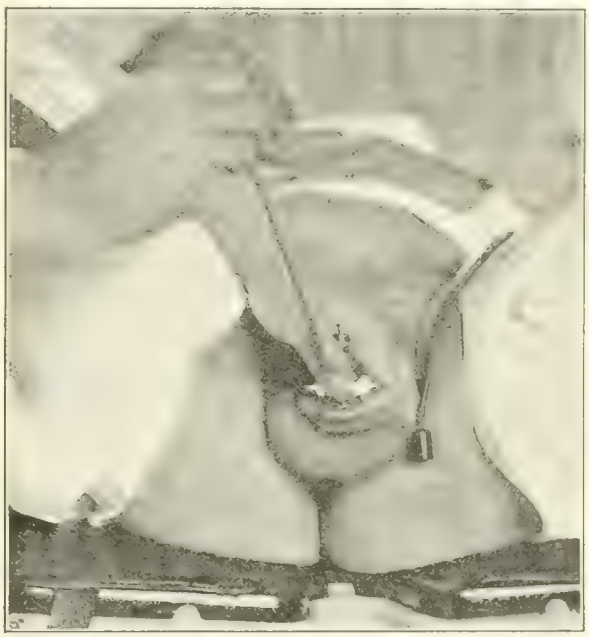

Fig. 2.—Just before the introduction of the telescope.

The use of the cystoscope, in its broadened field of utility, deserves to receive from members of the medical profession a thorough consideration. This is especially true at this particular time, when testimony in the shape of writings and teachings of many observers, derived from actual experience, present deductions worthy of the keenest interest and investigation.

Cystoscopy is a procedure that is practical and reliable. It is a diagnostic measure of marked value, for by its use can often be determined the location or the cause of obscure bladder and kidney affections. We gain knowledge of the exact condition of the mucosa and are thus enabled to determine the best remedial agents to be employed. The presence of tumors, anatomical deviations, the state of the ureters, the vascular supply or the activity of the kidneys, are but a few salient points readily attainable. Again, and perhaps more important, the cystoscope enables catheterization of the ureters and the collecting of the separate urines, the microscopical findings of which serve to establish a diagnosis and thus enable us to apply such topical medicaments as are indicated. Strictures of the ureter can be dilated. The presence of suspected calculi can be made certain, and their removal possibly accomplished. Drainage of a kidney can be facilitated. Ureteral and pelvic irrigation can with safety be performed.

As newer cystoscopes are perfected the operative field will become larger and larger; finer and neater but effective, instruments will enhance the performance of delicate operations as yet impossible or perhaps unknown. With care, gentleness, and proper equipment it can be truly stated that, although this special work is as yet rather a new departure, it promises to yield good harvests as one of the more modern fields of scientific research. This paper cannot more than touch upon the really operative work, as the intention is only to offer a few suggestions found valuable to the writer, with the hopes that to others they may prove of interest and value.

Indications for, and Conditions Governing Treatment.—(1) From microscopic examinations of the mixed urine and from the clinical history of the case we obtain information justifying the procedure. (2) A consideration of the nervous and physical condition of the patient will teach us whether interference must be immediate or whether measures to render the operation less painful may first be employed. (3) The eradication of all conditions tending to interfere with the use of the cystoscope, such as stricture, enlarged prostate, sensitive urethra, or an irritable bladder. (4) The condition of the heart must receive special attention, for often surgical shock plays an important post-operative part.

My experience in cases thus far treated leads me

to believe it is always wiser, although not absolutely necessary, first to use bladder lavage a few times or, if the urethra is small or sensitive, at least to pass a sound. After such manipulation, in a little time it is surprising to find how well the cystoscope can be passed. Among women patients I have met with at least six cases of greatly inflamed and very tender

Fig. [illegible]—Telescope and catheter in place.

urethra. This complication was eradicated by the use of a soothing, healing urethral bougie and by giving bladder lavage for a few days. In men, the use of a sound soon causes the urethra to become tolerant. Where time cannot be taken for this preparatory work, I have found that a weak solution of cocaine or eucaine, or some soothing oil, also a

Fig. 4.—Withdrawal of the telescope, the catheter being held in position.

good lubricant, renders the operation almost painless.

A Few Good Rules to Observe.—All catheters should be perfectly clean. Formalin tablets, in a piece of gauze, kept in the tube or jar that holds the catheters, renders them antiseptic. Before use, the catheters are dipped in a mixture of alcohol, water, and formalin, then rinsed with hot water. The catheters to be used for the ureters are treated in the same manner, except that by means of a small, slim

Fig. 5.—Withdrawal of the cystoscope leaving the catheter in place.

needle attached to a syringe they are washed out with a mild, hot solution of formalin.

Cystoscopes are dipped in the formalin solution, then rinsed thoroughly in water. It will be found useful to pull over the outer ends of the catheters

Fig. 6.—Collecting the separate urines

short pieces of small rubber tubing stopped with tiny wooden plugs; this expedient will prevent the catheters leaking while in the bladder. Always test the light, making sure the current is just the right strength. Always have the hands and arms perfectly

clean, as the operator should use as much care as if he were to perform a major operation. If an irrigating cystoscope is used, have the small piece of tubing in place, as if needed later it cannot then be easily applied. Place all instruments upon a sterilized towel on a table near at hand. Also place where they can be readily reached when needed two test tubes and corks that have been thoroughly boiled. Wipe the tubes dry and mark respectively R. and L. and also with the patient's name, using a pencil specially prepared for writing upon glass. Distilled water is the best medium for the lamp; a few drops of formalin can be added. The irrigator or, if a hand syringe is used, a basin, is filled with this preparation.

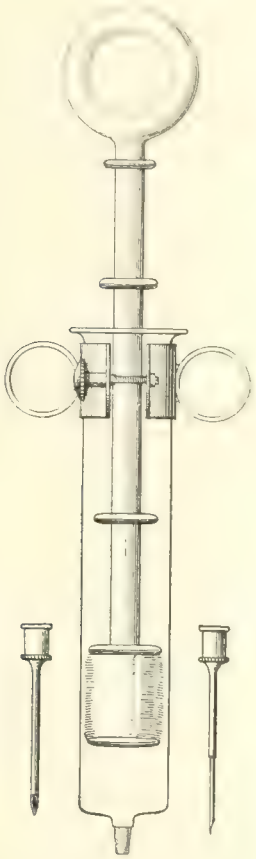

Fig. 7.—Syringe for renal lavage.

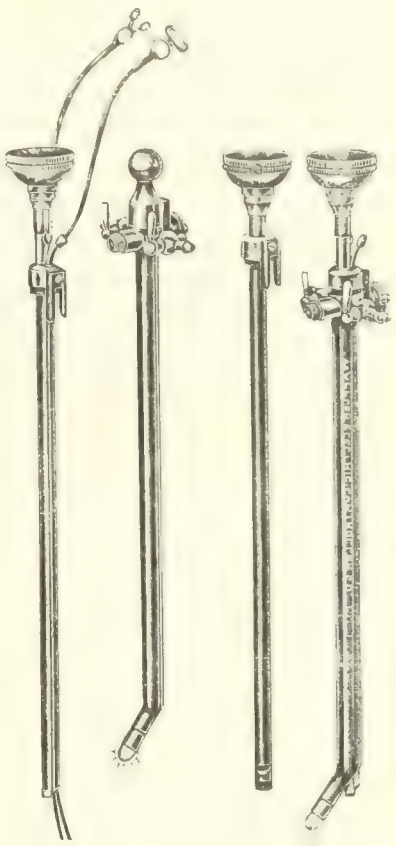

Fig. 8.—The Brown ureter-catheterizing cystoscope.

Method of Procedure.—In private practice I find it of decided advantage to have both men and women remove their clothing and put on white pajamas, the drawers having been cut out a little to furnish sufficient room for the operator to handle all instruments without any hindrance whatever. The patient now lies upon the table, his legs in stirrup rests, or if on an ordinary operating table, caught in slings at the posts. It is wise to raise the part of the table on which the patient rests to an angle, as a better view of the bladder can be obtained. The catheter is gently introduced and part of the fluid thrown into the bladder and allowed to run out. This is repeated until the fluid comes away clear. A little one per cent. cocaine solution injected into the bladder just before filling makes it more tolerant. Finally allow as much water to remain in the bladder as the patient can retain with comfort; certainly much less than three ounces renders much more difficult the work to be done. The catheter is then removd and the cystoscope is slowly and carefully inserted. The first motion is much like passing a sound, but the latter part of the introduction is essentially different and is difficult to explain in words. One must see this done, and also do it very often, before skill will be attained. The attempt is made in the following series of photographs, to show the method of introduction.

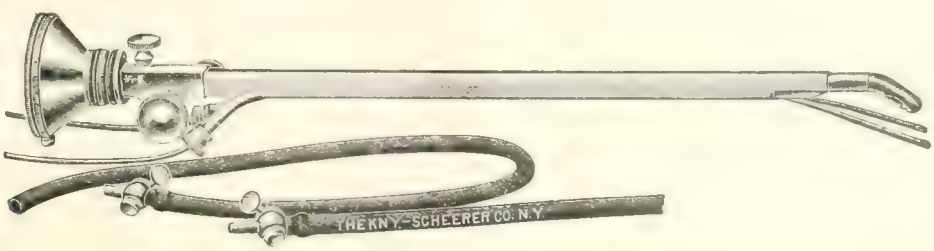

Fig. 9.—The Bierhoff double-channel ureter-catheterizing cystoscope.

Suppose the cystoscope is well in the bladder; the under screw is loosened and the solid rod removed, holding the fingers at point of egress to prevent too much water escaping. Telescope and catheters, or plain telescope, are quickly inserted. Attach wire to cystoscope and turn on the light. If the catheters have been introduced, the ureters are sought for; when found, a catheter is pushed gently into the orifice and the sense of touch depended upon to

determine just how far it shall be inserted. The opposite ureter is located and entered. The light is now shut off and the telescope removed, the catheters being pushed back towards the bladder. The water is allowed to escape. Both catheters are now slowly directed towards the bladder as tube is removed. In the male a slight pressure over the perineum holds them while the tube is completely withdrawn. It is safer to use black and light colored or have one of the catheters striped or the end of one painted black, so that the right and left are clearly marked. The separate urines then are collected in the test tubes.

Lavage of the kidneys consists in the direct application to those organs of some preparation, boracic acid solution containing silver nitrate, strengths from 1-12,000 up to 1-7,000, or ½ of 1 per cent. of one of the organic silver salts, or a healing oil, an astringent, or a hemostatic. There are no standard solutions; experience is the teacher and conditions found, the guide. Only a small amount (15 to 30 minims) should be injected at any one time; a total of from 1 to 4 ounces can be used at each lavage of both kidneys. Each catheter is then removed in turn, a good plan being constantly to inject some of the fluid during withdrawal, as then the whole urinary tract is influenced and receives a thorough washing out. Lavage of the bladder is conducted by Janet's method with a warm solution of boracic acid, or 1-5,000 solution of silver nitrate, or a combination of boracic acid with some one of the silver preparations. A fair amount is left in when the catheter is withdrawn; this, when passed by the patient, thoroughly cleanses the urethra. The needle for instilling fluids into the kidneys is like that of an ordinary hypodermatic syringe, except that it is made blunt. It is attached to the syringe, the capacity of which should be an ounce or more. If an air cystoscope is employed, the first wash is of course not necessary. More cocaine will probably be needed. An operator should understand the use of all the well-known cystoscopes, for at times it is impossible to perform the operation with the one instrument with which he is familiar and resort to others becomes necessary.

Difficulties that May Be Encountered.—Even when catheters are in place no urine may collect in the test tubes. This may be due to the small holes becoming plugged with mucus, thick pus, etc., or to very inactive kidneys. When this occurs, inject a small quantity of warm sterilized water, or a warm saline solution, and the difficulty is overcome. The fluid in the bladder may be so tinged with blood that nothing can be made out. If this happens, keep injecting fresh clean water through the tube attached to the side nozzle until a clear field is obtained. Abnormal deviations may be present in the shape of ureters that are widely separated; the orifice of one may be high, the other one low; one may be seen plainly on the white surface, the other in the red; one may take a catheter easily, the other may require a sharper and smaller catheter. When endeavoring to locate the ureters, watch for the swirl of the urines as a guiding factor. By tipping the patient up higher the ureters may appear that were lost to view. Stricture of the ureter renders the passage of a catheter impossible; dilatation is then demanded. Growths in the bladder often cover up the ureteral openings; interference of some sort is then required before catheterization is possible. Spasms of the bladder and the nervous straining and moving of patients frequently prevent any attempt meeting with success; these demand especial attention in order to avoid failure. Lamps grow hot, and burns are caused if too much time is consumed in the examinations. It need hardly be stated that these do not represent all the perplexing difficulties that may arise, but as fair examples they are sufficiently suggestive.

Descriptive Cases.—What are the cases, then, that may be cured or improved by lavage of the kidneys? The following illustrative cases from among the patients treated during the past year have been selected for two salient reasons: first, because all ordinary remedial measures had been tried and the conditions did not change for the better, and second, they serve as decisive examples of certain classes. The time has been sufficiently long to prove that results are permanent.

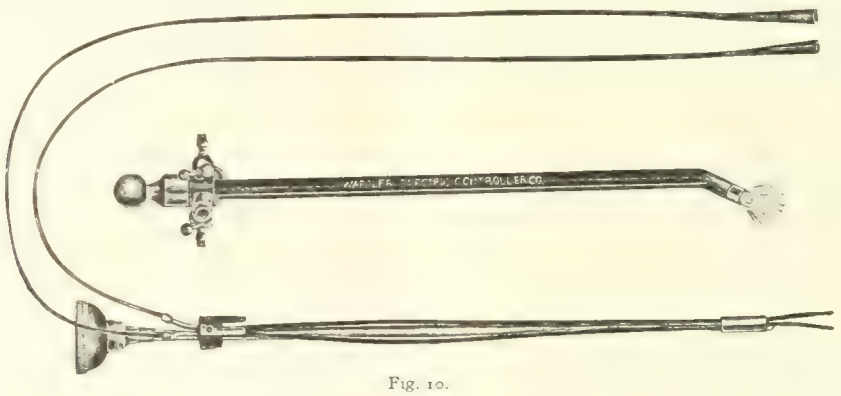

Fig. 10.

Case I.—Miss G. M., age 29. History obtained: For two years had suffered from headache, backache, loss of appetite, restless sleep, an utterly tired-out feeling at all times, but especially in the morning. Frequency of urination during both day and night. Attacks of melancholia at times. A growing nervous irritability. Fleeting pains in legs, knees, hands, and arms. No relief from either dieting or medicines. Change of scene and air improved the condition for a time only. Of late constipation has been present and there has been marked vomiting or nausea. Patient feels so utterly miserable that she says unless relief can be obtained she does not care to live. Physisical condition: Poor circulation, nervous heart action, marked anemia. Tenderness over region of the kidney and lower part of spine. Flesh soft. Lungs and bronchial tubes most sensitive. No trouble with the uterus, vagina or ovaries. Urethra normal. From examination of the mixed urine was made the diagnosis of lithemia, causing a chronic catarrhal

pyelonephritis and a mild chronic catarrhal cystitis. Catheterization of the kidneys was readily performed. Right and left urines each showed the existence of lithemia, with chronic catarrhal pyelonephritis. The left kidney gave evidence of more disturbance than the right. Treatment was instituted as follows: Kidney lavage with ½ of 1 per cent. protargol in a ½ saturated solution of boric acid. This was given warm, once a week. Bladder lavage consisted of 1-5,000 silver nitrate in a ½ of 1 per cent. saturated solution of boric acid given every two or three days. Internally, piperazine water—a quart during the day—and 20 drops of dilute nitromuriatic acid in orange-flower water after each meal. A tonic before meals. Hypodermic injections of ergot and then strychnine were also used, at first daily, then twice a week. Outdoor exercise and stimulating baths were advised. After a time piperazine was stopped, also the acid, and an effervescing lithia salt used before breakfast, the tonic being continued. Treatment has lasted about two and a half months. Patient's condition is again normal. Her appetite is good and digestion is perfect. Has neither headaches nor pains. Enjoys life. Has made a decided gain in flesh. The flesh itself is firm and hard. Examination of urine last made showed no albumin, normal specific gravity, no oxalate of lime crystals. But few uric acid crystals. Microscopic findings of the sediment from the right and left kidneys, show evidence of only a slight irritation of the kidneys. Virtually the patient may be regarded as well. As treatment has been given in detail, it can easily be seen that the beneficial effects of lavage must have been the factor causing recovery, for only very simple medicines were prescribed. Many cases of stubborn lithemia or oxaluria have responded even more quickly to such measures. Here a little longer time was necessary, as the affection of the kidneys was more pronounced.

Case II.—Mr. T. N., age 22. No history of disease, as there were no subjective symptoms. Patient had kept at his work and only consulted me because he had been rejected for life insurance; the cause stated was presence of albumin. I was unable to obtain from him any history of disagreeable symptoms. In appearance he seemed to show only slight anemia and was not heavy enough for his height. Diagnosis from the mixed urines was subacute parenchymatous nephritis and catarrhal pyelitis; also lithemia. Both the right and left specimens contained hyaline, epithelial and granular casts. In about twelve days there were fewer casts, the lithemic condition being one of very mild pyelonephritis. There is still a mild lithemia. The patient has gained some six pounds in weight. The case possesses interest as showing a rapid response to local application in the kidney.

Case III.—Mr. E. H., age 61. History of illness for more than two years. Principal symptoms had been headache, nausea, indigestion, weak heart, dropsy, partial lack of ability to walk, loss of flesh and strength. Had received treatment from many physicians and at a hospital was told he had but a short time to live. Disfiguring skin eruption on face. Had taken large quantities of digitalis and iron. On examination a stricture of the urethra was found. This was dilated. Prostate was also enlarged. Urine examination showed the case to be one of chronic parenchymatous nephritis and chronic catarrhal cystitis, there being a fairly large amount of albumin. Both kidneys were treated with ½ of 1 per cent. protargol in boric acid solution. In all there were some eighteen cystoscopies and in the interim bladder was washed out with 1-5,000 silver nitrate. Salol, alkalies, and piperazine were the internal remedies employed, no digitalis being used. To-day the patient shows marked improvement. He has resumed work, has a good appetite and has gained sixteen pounds in weight, his flesh being much firmer. Right and left urines show no appreciable albumin; microscopic features are scanty. No casts are found. The diagnosis now is chronic catarrhal pyelonephritis. While the patient cannot be called cured, the improvement is decided. Measures other than lavage had utterly failed to bring relief.

Case IV.—Mr. L. F., age 46. For four years had complained of pain in right side in region of kidney, loss of strength and flesh, frequent micturition, indigestion, etc. Pain so severe that morphine had to be used. Urine examination showed chronic catarrhal pyelonephritis with acute recurrence and also suggested a suppurative process. Constitutional condition poor. This was in July, 1904. Early in September patient was catheterized and urines collected. Right chronic nphritis, probably suppurative in character; catarrhal pyelitis. Left-chronic catarrhal pyelonephritis. A stricture was found in right ureter near opening, but fluid could be forced in fairly well. Pus could be seen flowing from the ureter. Patient lived quite a distance away, but as a rule managed to have the operation done once in ten days. He was taught how to wash out his bladder and learned to do this very well. Salol, urotropin, tonics, and cathartics were alone required, as pain disappeared after the first lavage. January, 1905: The specimens show no evidence of the previous suppurative inflammation, the right now showing a chronic pyelonephritis only, while the left is nearly normal. The stricture has not yet been overcome, as it has been impossible to pass the dilating bougie into the right ureter. Patient has not lost a day from his work since treatment was begun. No calculus has ever been found and no reason for the condition first found in the right kidney has been ascertained.

These cases illustrate how different conditions are influenced by appropriate local measures. Many others could be cited, but none would show any more clearly what this procedure can accomplish.

43 Tremont Street.

THE DISORDERS OF THE NERVOUS SYSTEM ARISING IN THE COURSE OF CHRONIC NEPHRITIS.*

By WILLIAM M. LESZYNSKY, M.D.,
NEW YORK.
ATTENDING NEUROLOGIST TO THE LEBANON HOSPITAL; CONSULTING NEUROLOGIST TO THE HARLEM HOSPITAL, AND THE MANHATTAN EYE AND EAR HOSPITAL.

Chronic nephritis is often so insidious in its development that its accidental discovery in a large proportion of cases is due to some obtrusive symptom which leads the unsuspecting patient to seek medical advice, while slight functional disturbances in the various viscera or nervous system may have been ignored or misinterpreted for a long time. Unfortunately, in many instances of this disease, especially of the interstitial form, in which the condition may exist without any actual discomfort to its victim, the true nature of the slighter nervous manifestations is not recognized until some serious or fatal complication takes place.

When we consider that the involvement of the nervous system is, on the one hand, due to toxemia, while on the other it is directly attributable to ar-

*Read before the Harlem Medical Association, March 1, 1905.

terial degeneration interfering with the nutrition of the cerebral structures, and that the coexistence of both factors is of common occurrence, it is not at all surprising when we have occasion to note in an individual case many of the following symptoms: Cephalic paresthesiæ; headache in various degrees to true attacks of migraine; insomnia; numbness in the extremities; neuralgic pains in different parts of the body; vomiting; muscular twitching; monospasm or hemispasm to general epileptic convulsions; amaurosis; deafness; transitory attacks of aphasia; facial paralysis; paresis or paralysis of one extremity; hemiparesis, hemiplegia or paraplegia; gradual or sudden coma; delirium; stupor; insanity; and permanent hemiplegia with or without aphasia.

The above mentioned disturbances are almost exclusively of cerebral origin, being indicative of irritation or destruction of various nerve centers or tracts. The symptoms due to uremia *per se* originate mainly in the cortex, thus interfering with the function of the nerve cells directly, or secondarily through involvement of the vascular supply. The occurrence of uremic focal symptoms renders this supposition the more likely.

Various cephalic paresthesia may be complained of, such as a sensation of pressure, fullness, throbbing, etc., analogous to that experienced by neurasthenic subjects. Headache in diversified forms may be one of the earliest and most persistent of the series of symptoms occurring in the course of chronic renal disease. Several writers on general medicine have endeavored to describe a special type of headache due to uremia. Ordinarily the pain is situated in the occipital region, and is often bilateral, extending to the back of the neck. It may or may not be associated with somnolence, nausea, or vomiting, etc., according to the degree of damage to the kidneys or arterial system. But the headache itself possesses no distinctive characteristics which will permit of its classification in any pathognomonic type. There may be periods of headache accompanied by vertigo, and mental confusion, which are often erroneously ascribed to cerebral hyperemia. Headache may also be of a congestive type in patients with high blood-pressure, arteriosclerosis and pronounced ventricular hypertrophy. I have often observed the coexistence of severe and persistent general headache with vomiting, vertigo and optic neuritis (or the erroneously so-called albuminuric retinitis) simulating the general cerebral symptoms of brain tumor or basal meningitis.

In some instances there may occur periodical attacks of severe unilateral headache followed by vomiting, thus resembling an attack of migraine, and nephritic patients have been treated for this neurosis for a long time before the discovery of the underlying pathological process.

In some of these cases true migraine may have existed for several years before the development of the renal disorder. Rosenstein states (Die Pathologie und Therapie der Nierenkrankheiten, p. 257) that "Migraine is often the only symptom that patients with smooth or granular contracted kidneys complain of, and that he has often observed that such patients, in spite of the chronic course of the nephritis, present more or less constant edema and great pallor of the face." Insomnia is also a frequent symptom, and is usually due to the accompanying cerebral endarteritis.

Uremic vomiting, which is often an extremely obstinate symptom, is in many instances of cerebral origin, being analogous to the type of vomiting which so frequently accompanies intracranial disease. As previously mentioned, when optic neuritis and headache are also present, the condition has been mistaken for cerebral tumor.

Neuralgic pains in different parts of the body often arise in the course of chronic nephritis. Cutaneous hyperesthesia, such as a sensation of severe burning and itching, may occur, which at times terminates in intense neuralgic pains. Such pains, if they involve the muscles, may be incorrectly interpreted as being of rheumatic origin. Supraorbital neuralgia also occurs occasionally. Of course, it is probable that all of these subjective sensory disturbances are purely of toxic origin, being either uremic or due to defective metabolic processes.

The special senses may also be affected. Bilateral amblyopia or complete blindness may develop suddenly or very rapidly, and may occur independently or follow a convulsive attack, or it may be preceded by headache, nausea, and vomiting. In uncomplicated cases, as a rule, the pupillary light reflex remains intact, indicating the cortical site of the lesion, and the ophthalmoscopic examination proves negative in its result. Restoration of vision is sometimes sudden and complete. But in some cases the pupils fail to react to light and there is ophthalmoscopic evidence of stasis in the optic papillæ. Hence the optic nerve or the primary optic ganglia must be implicated. Uremic blindness is more frequent in those forms of nephritis in which uremic attacks are common, as it occurs in scarlatina and pregnancy. It also arises during acute exacerbations in patients with chronic nephritis. Blindness may also form part of a general uremic attack, and persist after all other symptoms have subsided. It is at times associated with other cerebral symptoms, such as aphasia, hemiplegia, etc. Difficulty in hearing or complete deafness ocasionally arises as a symptom of uremia. Involvement of other special senses is very rare.

Muscular twitching is of common occurrence in uremic subjects, and together with headache, somnolence, vertigo, obscuration of the visual fields, and dyspnea, constitute the usual premonitory symptoms of a uremic convulsion. Such patients may be suddenly seized by a general convulsion, which is in all respects an exact counterpart of the true grand mal attack of epilepsy. Under these circumstances, the differentiation of the convulsion from genuine epilepsy can only be made from the presence of additional phenomena peculiar to uremia and chronic nephritis. The clinical history, the presence of edema, cardiac hypertrophy, and, possibly, gallop rhythm, and the condition of the urine will reveal the true nature of the trouble. According to Blondeau (Recherches sur l'urémie fébrile, *Thèse de Paris,* 1892), "when the fits assume the form of status epilepticus in the course of uremia, the temperature may even be subnormal, but in the present state of our knowledge, rise in temperature cannot be considered as excluding uremia." We should therefore always be on our guard before making a diagnosis of epilepsy, when the first known convulsion occurs in a patient over forty years of age. In rare instances, however, uremic convulsions may occur without disturbance of consciousness, and they may be entirely unilateral, and thus simulate Jacksonian epilepsy, as in the following case: A man fifty-two years of age had complained of occasional headache for several weeks. On awaking one morning he noticed twitching of the left hand. In a short time the arm, leg, and face on the same side became similarly affected. These spasms had continued for several hours. When I saw him at 1 P. M. of the same day, with his physician, the late Dr. F. W. Merriam, of this city, he was lying abed,

perfectly conscious and without any disturbance of speech. He merely complained of slight general headache and of the annoyance and alarm occasioned by the muscular spasm. The pulse beat was 76 to the minute and of high tension. Respiration and temperature normal. There were indications of slight hypertrophy of the left ventricle and distinct accentuation of the aortic second sound. The pupils, ocular fundi, and all reflexes showed nothing abnormal. Every two or three minutes there occurred a violent unilateral clonic convulsion, involving the left face, arm, and leg, lasting a minute and a half, and followed by muscular relaxation, slight twitching continuing until the next attack would occur. There was no paralysis.

He complained only of aching and fatigue in the arm and leg, and said that the movements were beyond his control. I watched him for nearly an hour. The urine was diminished in quantity and contained much albumin and an abundance of hyaline and granular casts, etc. Similar cases have been observed by Rosenstein, Senator, and others, but are very rare.

At times acute uremia may manifest itself by slight stupor, delirium, or coma, without any signs of twitching or convulsion, the coma becoming profound and terminating in death within 24 or 36 hours. These cases are often mistaken for cerebral hemorrhage, although a careful study of the patient will generally make the diagnosis clear.

Several years ago I was called by a physician to see a lady on Long Island. The patient, who was about fifty years of age, had been comatose for several days. Before lapsing into coma she had suddenly become deaf and totally blind, and had for several weeks complained of severe headache and occasional vomiting. During the condition of coma she had been examined by several physicians and various diagnoses made—cerebral hemorrhage, brain tumor, septic peritonitis, etc. No urine had been voided in 48 hours, yet examination showed that the bladder was not distended. Pulse very rapid and feeble, temperature 105°, Cheyne-Stokes respiration, cardiac hypertrophy, and a distinct urinous odor to the profuse perspiration and edema over both ankles. In other words, a classical case of uremic coma. The urine had not been examined. She died a few hours later. The autopsy, made by Dr. Frank Ferguson, of this city, revealed advanced disease of the kidneys. Such a case is a commentary in itself, and requires no further elaboration or criticism.

It is well known that patients with chronic nephritis are likely at any time in the course of the disease to develop some form of paralysis, which may be either transitory or permanent. Attacks occur which may last from several minutes to a few days, such as aphasia, facial paresis or paralysis, monoplegia, hemiplegia, or paraplegia, in varying degree from slight loss of muscular power to complete paralysis. These evanescent or ephemeral attacks, even of a very mild type, may precede or follow a uremic convulsion or coma, or may occur independently, as in the following case:

A lady fifty-four years of age complained of weakness and numbness of the right half of the body and extremities, lasting ten or fifteen minutes, preceded by slight headache and muscular twitching. She feared impending paralysis, and became anxious and apprehensive. The attending physician attributed the symptoms to "only nervousness and hysteria," as he told me. The patient was found lying abed, more from fear than actual discomfort. There were no indications of involvement of the nervous system, but there was high arterial tension and slight ventricular hypertrophy. Examination of the urine on the following day revealed unmistakable evidence of chronic nephritis. Death occurred in uremic coma about ten days later.

These attacks are due to arterial thrombosis, vascular spasm, or localized cerebral edema. Many instances have been reported in which nephritic subjects have become completely hemiplegic several days before death, and at the autopsy nothing has been found to account for the paralysis but apparent cerebral edema or dilatation of the lateral ventricles. Hence in medical textbooks we read of "uremic hemiplegia" designated as due to localized cerebral edema. It has seemed to me that vascular spasm, *i.e.* spasmodic contraction of the muscular coat of the middle cerebral artery, might explain many of these cases, the edema being the result of the arterial obstruction. It has been assumed by Peabody (MEDICAL RECORD, 1886, V. 30, p. 65) that the vascular spasm may be prolonged to such an extent that life terminates before the spasm ceases, though the duration may not be long enough to cause softening of the brain area affected. It is a significant fact, however, that in none of the patients in whom such attacks have occurred have normal cerebral arteries been found at the autopsy. In other words, the condition is always an accompaniment of arterial degeneration.

Recently Weisenberg (*Journal of Mental and Nervous Diseases*, July, 1904) published the histories of two patients, aged 71 and 77 years, respectively, in whom permanent hemiplegia developed within two weeks before death. As no gross lesion was discovered at the autopsy, he has combated the theory of localized cerebral edema by endeavoring to explain the hemiplegia as due to primary degeneration in the nerve cells of the brain and spinal cord, and involvement of the motor fibers, as this was found in both cases upon microscopical examination. These pathological findings, however, were no doubt primarily due to the arteriosclerosis which was admittedly present.

As we are still uncertain as to the exact pathology of so-called "uremic hemiplegia," we must conclude from the present state of our knowledge that these symptoms are the result of arterial degeneration. The correctness of this view receives substantial confirmation in the common occurrence of similar cerebral symptoms in patients with endarteritis from other causes, in the absence of chronic renal disease. If these facts are borne in mind, the prognosis as to the duration of the paralytic symptoms would generally be more guarded.

Many cases of chronic nephritis run a prolonged course without any serious signs of uremia, and yet the accompanying degeneration of the cerebral vessels is sufficient under suitable circumstances to induce thrombosis and acute cerebral softening, or the rupture of a vessel followed by unconsciousness and death or a permanent hemiplegia. Cases galore of this kind could be cited from the clinical experience of every practitioner. Such conditions are to be expected, and are of rather common occurrence. In the former the blood-pressure in the radials is not perceptibly increased, while in the latter high vascular tension is usually present.

As a rule, the more severe complications, which often terminate in rapid death or permanent hemiplegia, are due to the arterial disease *per se*, and usually have no immediate connection with uremic intoxication. At times, however, a uremic convulsion may be followed by cerebral hemorrhage and hemiplegia.

In some cases of chronic uremia the motor symptoms are not so pronounced, while the mental symp-

toms become more obtrusive. They are usually delirium and hallucinations. Disorientation may be a prominent manifestation, the patient not recognizing his surroundings, wishing to go out undressed, and imagining himself in a strange place while at home. Several cases have been observed in which a direct relation existed between the psychical disturbance and diminished secretion of urine. But the above-mentioned phenomena are more or less similar in character to those arising in other forms of toxemia. Consequently they present nothing distinctive which would enable us to place them in a special category as indicative of renal disease. Occasionally these symptoms may develop into a maniacal attack or be followed by mental depression.

I have repeatedly seen patients over fifty years of age with only very slight evidence of chronic nephritis, who suffer from insomnia, occasional apathy, mental confusion, forgetfulness, and visual hallucinations, evidently due to uremic poisoning, but also attributable to the concomitant cerebral endarteritis. Chronic nephritis is, however, commonly observed from its early development to its termination without any mental impairment whatever, and it is a well-established fact that renal disease is an unimportant element in the causation of insanity.

We should always reserve our diagnosis as to the origin of such nervous manifestations as those herein enumerated, in the absence of evidence of kidney disease, until a careful study of the urine has been accomplished. It is hardly necessary to say that this is practically axiomatic, and should be a predominant feature in the clinical observation of all patients in the fifth decennium. Too many physicians limit such analysis to a test for albumin, and formulate their conclusions accordingly, although it is just in these cases of cirrhotic kidney that albumin is often absent. Sometimes it is quite difficult—nay, well nigh impossible—to reach a definite diagnosis as to the presence or absence of renal disease from the examination of a single specimen of urine. In making the diagnosis of chronic nephritis in a doubtful case it is more essential to consider the amount of urine secreted every twenty-four hours, its specific gravity, and the amount of urea or solids therein contained, than to lay stress on the presence of a trace or more of albumin and a few hyaline casts, especially when the patient under consideration is about fifty years of age or more. The estimation of the percentage of urea or solids in the urine, however, is of comparatively little value unless considered in connection with the amount of food consumed by the patient and the condition of his metabolic processes. Nevertheless, frequent and complete chemical and microscopical examination of the urine should be a routine practice.

In the correct interpretation of many of the symptoms described in this paper, one must always bear in mind the possibility of the presence of hysteria, as well as cerebral endarteritis from other causes. Although hysteria may be associated with almost any form of structural disease, the principles of modern neurological diagnosis require the exclusion of organic disease of the nervous system and the internal organs before considering hysteria as the predominant factor.

It will thus be seen that, aside from the various neurasthenic manifestations occurring in patients with chronic nephritis, many of the transitory *subjective* nervous phenomena arising during the course of the disease are the result of uremic (or possibly other) intoxication in varying degree, while nearly all of the transitory *objective* nervous phenomena, and the more permanent and incapacitating or fatal complications, are primarily due to the concomitant arterial disease. Hence palpable evidence of arteriosclerosis and high blood-pressure are usually of the greatest significance. While some believe that chronic nephritis may cause arterial degeneration by preventing suitable elimination of toxic products which enter the circulation, increasing the vascular tension and injuring the walls of the vessels, others are of the opinion that in many cases the arterial changes cause the renal disease. Both views are doubtless correct, for there is often considerable variation in the type of the disease. But such an etiological differentiation in an individual case is generally impossible. It is not at all surprising, therefore, that involvement of the nervous system is so frequent during the course of chronic nephritis, for arterial degeneration has for a long time been recognized as an important (and often the chief) factor in the causation of many organic nervous disorders.

The brief histories relating to incorrect diagnosis outlined in this paper have been selected from a large number of similar observations, and are merely mentioned to emphasize the well-known but deplorable fact that many of the seemingly insignificant or apparently trivial symptoms which arise in the course of unrecognized chronic nephritis as a rule do not receive the attention that their gravity merits.

THE TREATMENT OF ECZEMA AND IMPETIGO IN CHILDREN.

By CHARLES W. ALLEN, M.D.,

NEW YORK.

Unfortunately for us, eczema still remains a subdivision of the list of cutaneous affections into which are placed a variety of inflammatory diseases of different nature.

Fortunately, however, the type of infantile eczema of the face, which is the most frequently encountered, is a clearly defined condition in its several forms. These include E. seborrhoïcum, E. impeliginodes, E. madidans, E. papulosum, E. pustulosum, E. vesiculosum, E. rubrum, E. squamosum, etc. These terms all relate to the appearance, and do not aid us in forming an idea of the etiology, though the name often suggests the line of treatment most likely to benefit and thus far is of advantage. The type is seldom clear—eczema must be regarded as polymorphous. A case which begins as erythematous may soon change to a scaly, pustular, crusty or oozing surface.

The most we can do in nomenclature is to so name the outbreak that it indicates which type predominates at the time, since several may coexist or follow each other. Scratching and infection are the causes of much of the change occurring in individual plaques. A form of infantile eczema often encountered may be termed eczema intertrigo—implicating the region of the buttocks and genitals. It begins usually as an erythematous intertrigo and becomes exudative, with great redness and irritation, intensified by secretions, maceration of the parts, contact with urine, feces, heat of diapers and clothing. It may, too, begin in the folds of the groins as a seborrhoic dermatitis and undergo subsequent changes.

There is another form, showing vessiculation, and at times edema, which has been described in nursing infants as tuberculous. The term is faulty, as the condition has no proven connection with tuberculosis.

It attacks the natural orifices adjacent to and often implicating the mucous membranes.

There is usually to be found some antecedent affection of the mucous membranes of the eyes, nose, ears, or mouth, and otorrhea, nasal discharges, or

some eye or mouth affection may coexist. The course is chronic and there is marked tendency to recurrence. The adjacent lying lymph nodes enlarge and there is general debility present in some form, calling for internal medication. The type of child is often what may be termed "scrofulous."

It is evident, therefore, that having these possibilities in mind, the treatment of any given case must depend largely upon the view we take of the origin and nature of the affection. It is not scientific to say, "Zinc oxide ointment is good for eczema," no matter how near to the truth this statement may come. We must distinguish, too, between the acute and highly inflamed and irritable forms and the chronic varieties and stages in which occur thickening, fissures, excoriated wounds from scratching, and obstinate superadded infectious processes

While in a general way it may be admitted that improper feeding, faulty digestion, and assimilation are at the bottom of persistent and obstinate infantile eczemas, the clinical fact remains that the vast majority are susceptible of cure by local measures alone. Most of the infants in my public services have given no indication of disordered digestion, and the greater part of them have recovered without making any decided change in their feeding. In the very young the mother's breast has furnished the sole nourishment, and, so far as appearances of both child and mother indicated, there was no change called for further than perhaps to regulate the hours of nursing. The health of the mother and quality of milk are important. Manufactured foods and sweet condensed milk are to be avoided as a general proposition. The indications are usually to soothe and protect a highly inflamed, pruriginous area, and secondarily to destroy germs and act upon deeper infiltrations and dilated vessels. Naturally underlying constitutional defects must be remedied and all faults of diet corrected. In general it may be said that symmetry of lesion speaks for constitutional origin, asymmetry for local cause.

In the choice of local remedies we must, as I have said, be governed by causative conditions, stage and state of the affection as it presents itself.

Among general local measures, to fulfill the objects of disinfection, protection, soothing and favoring the growth of new epidermis, I wish especially to advocate the use of methylene blue solution as originally, I believe, suggested by me, and employed almost as a routine practice where the disagreeable features of staining of clothing does not contraindicate its use. I employ a three to five per cent. watery solution as preferable to a stronger solution with alcohol, whose initial effect would be painful. In intertrigo and intertriginous eczema, I believe the remedy has no equal. Next to it probably comes a weak resorcin ointment followed by free dusting with bland non-caking powder.

My practice is to allow the solution to dry in well, and then apply quickly a thin layer of collodion. This is to be repeated, before the peeling collodion becomes of itself a source of irritation.

Nitrate of silver is a remedy too often neglected, perhaps, in chronic infiltrated and especially obstinate forms of eczema. It is especially useful in crusted eczema about the mouth and lips, where moisture favors constantly renewed infection. It can be used in from five 5 to 20 per cent. strength, to be followed by bland ointments, lanolin, etc. The crusts can be removed beforehand with oil dressings, or 5 per cent. salicylic ointment. Salicylic acid has great worth, especially in eczema of the scalp, crusted and desquamating forms. It can be used in the form of Lassar paste or in ointment. When decidedly stimulating effects are sought, a lotion of oil of cade, green soap, and alcohol in equal parts may be applied at long intervals. In pediculous dermatitis of the scalp, faultily termed eczema, one of the mercurials, either white precipitate or red sulphuret ointment in half strength may be used.

Resorcin is especially valuable in the seborrhoic forms. The milder 1 per cent. ointment alone, or with zinc oxide 10 per cent., usually suffices. Here, too, sulphur in mild form usually acts well. One important thing in nearly all eczema is the avoidance of much water. Nothing perpetuates a moist eczema more than frequent washing. Soap is often too largely at fault, latherings being applied with the erroneous idea that the badness can be washed away.

There is one pronounced exception to this rule about water, and that is in the seborrheal forms with greasy crusts and adherent masses of extraneous filth upon the scalp. These are as a rule washed often enough, but not intelligently vigorous enough. Water alone does not suffice. Warm oil should be rubbed in well beforehand and then the lather. Unless the scalp is maintained in a condition of healthy secretion and free from accumulations, it is not to be expected that the rest of the body will remain free. The areas of greatest sebaceous gland development are those characteristically implicated as a rule. In crusted impetiginous forms water is not to be withheld, but immediately after the bath antiseptic grease of some kind should be promptly applied. In the chronic infiltrated patches ichthyol has a useful field, just as in eczemas in adult life. A 50 per cent. watery solution makes a good varnish, as pointed out by Klotz, and this I make still more permanently adherent by painting over with collodion.

I know of no specific internal remedy. Arsenic has been much abused. I never employ it in the eczemas of young children. To avoid eczema in infants it has seemed to me that keeping the scalp in a perfectly healthy condition contributes more largely to success than any other single factor. It does not suffice to wash the scalp in the ordinary way. The greasy adherent scales "turn" the water and remain to give a resting place for dirt and germs. Green soap, salicylic acid, resorcin, sulphur, are all useful. A favorite prescription is: Resorcin, ½ to 1 per cent.; washed sulphur, 2 to 4 per cent.; lanolin, 5 to 10 per cent; and lard up to 100.

In more chronic forms of pityriasic eczema with much itching and falling of hair in older children, associated with scaly plaques upon the neck and involving especially the margins of the hairy scalp, I employ a stronger ointment, such as: Resorcin, 1 to 2 per cent,; liquid tar, 2 per cent.; calamine, zinc oxide, āā. 10 per cent. In treating the very frequently observed eczema of the cheeks, the chief problem is to keep our applications in contact with the skin. If the scalp is involved, the best way is to apply a bandage which covers in the whole area. This in private practice necessitates a nurse or daily personal attention of the physician, as the parent is rarely able to apply the bandage. To obviate this, I have devised a combination cap and mask. It is made from a single piece of stout muslin, thin canton flannel, or other material, not too thick. Sewed on or fastened with safety pins, this answers the purpose fairly well.

Among the poor, older children will often be found eating an excess of bakers' supplies, condensed milk, cereals, and canned food. Here changes in diet are naturally called for.

A judicious combination of restricted or regulated diet, internal measures when indicated and external

applications, will usually result in rather prompt cure for the majority of cases.

Impetigo Contagiosa.—Much injustice has been done the impetigo group by including it in the past with eczema. Impetiginous eczema must be distinguished from impetigo proper. An observation of my own, which is not acknowledged by most dermatologists and denied by many, is the frequent relationship of this disease to pediculosis capitis. In my experience it is rare to find this contagious auto- and hetero-inoculable crusted pustular and flat vesicular affection, occurring about the mouth, hands, and more or less generally distributed over the upper portions of the body in children, unless associated with pediculosis or traceable to lice in the head of playmates and associates, unless it has resulted from vaccination.

The term impetigo should suffice without the suffix contagiosa. Simple impetigo (Duhring) is extremely rare. It may be well, however, to retain the name as a constant reminder of etiology and prophylaxis. In diagnosis we must remember that there are serpiginous, circinate, and gyrate forms strongly suggested at times in ring-worm, clearing up in the center, much in the same way in both processes.

Now as to treatment. First of all, search for pediculi as possible disseminators or distributors and perpetuators of the affection. Remove crusts if necessary with potato flour poultice and apply a 10 per cent. ammoniated mercury ointment, or wash with green soap solution and then with 1-1,000 bichloride of mercury. For small areas, paint with 50 per cent. ichthyol in water, or 5 to 10 per cent. ichthyol in collodion. Salol diluted will answer as a dusting powder, or apply 1 per cent. Beta Napthol with 5 per cent. boric acid in vaseline. As a rule, however, ointments are not so good as washes.

For the scalp: 10 per cent. sulphur sublimate, ½ to 1 per cent. red sulphide of mercury in vaseline. In infants at the breast, milder ointments, such as salicylic acid and bismuth or Lassar paste, spread on cheesecloth and applied, will serve. It is only in the rarest instances that any internal measures will be called for.

30 East Thirty-third Street.

THE RELATION OF THE MEDICAL PROFESSION TO THE RESTRICTION OF TUBERCULOSIS.*

By S. P. WISE, M.D.,
MILLERSBURG, OHIO,
EX-MEMBER OF OHIO STATE BOARD OF HEALTH.

The tuberculosis question has assumed such a degree of prominence in medical and sanitary literature, that the medical profession can no longer afford to ignore it. The importance of the restriction and prevention of this great white plague appeals to all who have the welfare of humanity at heart, and should forcibly remind the family physician of a duty which plainly devolves upon him. It must probably be admitted that so far health boards and sanitary organizations have taken the lead in disseminating knowledge relative to this much-dreaded disease, and are, therefore, responsible for the agitation and awakening of public sentiment that now exists. This has been accomplished through the medium of sanitary literature and by the distribution of circulars, calling attention to the fact that the disease is contagious and to a large extent preventable.

*Read before the Fifteenth Annual Conference of State and Local Boards of Health of Ohio, January 27 and 28, 1905.

The public press has rendered some service in promoting the antituberculosis movement, but only to a limited extent. It has not been called into requisition as extensively in this country as it has in European countries. We should not fail to recognize that the newspapers are the great public educators of our country, and consequently are the most efficient weapons at our command. Therefore, one of the most important steps to be taken by the medical profession is to enlist in the cause every paper that is published throughout the country; from the great city papers down to the smallest publications that are issued in the villages and hamlets of the rural districts. None can effect this part of the movement so successfully as the family physician, of the editors and proprietors of these papers. Professional ethics should under no circumstances interfere with that which is for the public good. Printers' ink is the life-blood of quackery, and if properly utilized it is also the most powerful instrument for its destruction. For instance, if the profession of medicine were to put forth the same effort to teach the public all about tuberculosis as the impostors do in vending their nostrums, consumption cures would soon grow less conspicuous in public print, and quackery in this direction would eventually cease.

In the course of our educational and reform movement we must not overlook the periodicals which are devoted to the interests of religion, temperance, etc. It is a fact that papers of this class often contain alluring advertisements of alleged oxygen or ozone consumption cures, which are endorsed by flagrant representations for which there can be no possible foundation and no other motive than the almighty dollar. When we take a serious view of the matter and consider that a religious paper is supposed to be a messenger of truth, honesty and purity; and to contain nothing but that which is intended to promote the temporal as well as the spiritual welfare of humanity; and that, instead of this, it lends its influence to delude the unwary consumptive invalid, who by the very nature of his malady is the most gullible of all others; when we take all this in contemplation, we cannot else but denounce such action as an unpardonable outrage.

The clergy ought to render efficient service in educating the laity on the prevention of tuberculosis. Their influence and opportunities are in many instances greater than those of the family physician. They will no doubt enter into the work with zeal and enthusiasm if the matter is brought to their attention with due regard to its importance and seriousness. By an effort on their part, the participation in quackery indulged in by the organs of their respective churches can be suppressed, and their efforts directed toward the prevention of disease and the promulgation of the doctrine of rational hygiene. They must learn that there is no such thing as a "consumptive cure," that the scientific treatment of the disease consists solely in hygienic and dietetic measures, and that thousands of lives can be saved by observing very simple precautions. Laboratory experiments show that strong solutions of the best germicides known do not destroy the bacillus tuberculosis, even if brought into direct contact with the germ in its culture medium; so that when the claim is made that a chemical has been discovered that will destroy it in the human body, it is absolutely false. Sunshine and atmosphere, nature's great remedies, are the only reliable antagonists of the tubercle bacillus, and they extend to the consumptive individual the only hope of recovery. The poet aptly indicates the great panacea for tuberculosis in the following lines:

"Health dwells among the sun-kissed hills
And by the smiling sea;
Her maidens are the laughing rills,
Her pages wild and free.
The shifting winds that bear her train
Of fragrant wildwood flowers,
When skies are blue or mild with rain
Health rules the morning hours."

It is nearly a quarter of a century ago since Koch discovered the tubercle bacillus and identified it as the true medium of infection by which the disease is communicated. The results of his researches were soon corroborated by many other leading scientists. Since that time every phase of the subject has undergone the most exhaustive and painstaking scientific investigation that has ever been accorded any of the contagious or infectious diseases. As a result our knowledge of the disease is based upon an accurate understanding of its biology, as well as a clear conception of the chemical and vital phenomena involved in its diseased processes. Our conclusions in regard to the nature of the disease and its mode of transmission, are, therefore, positive and are far removed from all doubt and speculation. It is only in the last few years, however, that a spirit of agitation has arisen and is taking on the form of an organized effort toward the restriction of the disease. As before stated, this activity does apparently not arise from the medical profession at large, but seems to have been promoted by a limited few of its most prominent members, supported by health boards and sanitary organizations. The question is, therefore, pertinent at this time whether the rank and file of the medical profession are fully alive to the situation and whether they realize the enormous responsibility that rests upon them in the eyes of the scientific world, as well as in the estimation of the intelligent portion of the laity. History furnishes abundant evidence that medical men at all times and in all ages have been noted for their disinterested, self-sacrificing devotion to the cause of humanity, and thereby have often "killed the goose that laid the golden egg." They doubtless can be depended on again in this instance, although it would seem that they must be laboring under a certain degree of apathy since a discovery of such tremendous importance as the tubercle bacillus has been so slow in its practical results.

It is quite obvious that the family physician will constitute the man behind the gun in the tuberculosis crusade. The man who is personally intimate with the afflicted and his household, and holds their confidence, can accomplish more in educating the laity than can be inculcated in any other manner. It must be remembered, however, that to bring about a complete reform in the management of tubercular patients will be by no means an easy task, and in many instances will require tact and a liberal amount of patience. The educated and intelligent people who are even now well informed on the subject will practically take care of themselves. But the ignorant constitute the largest and most dangerous class, and it will be often difficult to overcome the prejudices and erroneous ideas which have held the sway for centuries past. Some consumptive persons seem to be possessed with a sort of stoical indifference, or even a feeling of actual resentment toward humanity in general. Regarding their condition as absolutely hopeless, they don't seem to care how many others they infect and consequently will disregard all precautions they are requested to observe.

Cornet relates an instance of a consumptive who lay sick at home and passed the time by seeing how high on the wall he could spit. In a few weeks after his death his wife and child both died of tuberculosis. The time is not far distant when a community can and will protect itself by legal measures against those who recklessly or obstinately persist in exposing the public to the infection of tuberculosis.
